Glossary

Taphonomy The study of the phenomenon affecting the remains of biological organisms at the time of and after death. The term means 'laws of burial' and was created by Efremov in 1940.

Scavenging Modifications of bones due to animal chewing in the postmortem period.

Scattering Dispersion and dislocation of bone fragments in the environment due to animal activity.

Introduction

The attack by animals is only one of the complex manifestations of the environment on the corpse, but undoubtedly brings about important modifications of the body or skeleton which may potentially hinder search and recovery as well as the assessment of lesions. Animals, in fact, are able to destroy

bodies, produce postmortem artifacts, modify the site of deposition, and scatter human remains, with a consequent decrease in the success of research and in the number of bones which may be recovered.

However, the scavenging activity has not yet been thoroughly studied experimentally. Several case studies exist but little research has been published. This is due to the difficulties

which are obviously associated with this phenomenon. First of all, scavenging is a stochastic event, which occurs in specific geographical settings and concerns the behavior of animal species inhabiting the area of interest. Literature reports that almost every animal species under specific conditions can attack a corpse: a very limited inventory includes leopards, foxes, hyenas, dogs, wolves, deer, sheep, hogs, rodents (porcupines, mice, squirrels, rats), crabs, turtles, fish, birds, and even golden hamsters: scavenging is also reported by domestic dogs or other pets, particularly in cases where they have been forced to remain in the same environment with the cadaver. Every geographic region is often inhabited by different species, which give their specific contribution to the consumption of a corpse, often in cooperation with other species. For instance, in cases of buried corpses, vultures use the opening made by raccoons during their scavenging activity in order to attack soft tissue and detach bone segments. Such a 'cooperation' is also characterized by different behavior: although animals usually scavenge corpses to feed on their soft tissues, other species are more interested in calcified tissues, such as rodents, who will gnaw on bones in order to reduce the length of their incisors. In addition, different species attack corpses at different times: vultures usually visit carcasses in the daylight whereas foxes, raccoons, opossums, and skunks act at night.

Experimental studies performed on pig carcasses have verified that bird scavenging tends to precede other scavenging activities, and is followed by canid activity, which initiates scattering. These few indications show that scavenging should be interpreted as a sign of the interaction between the corpse and a complex environment rather than the mere activity of animals producing different sets of lesions on bones; the phenomenon can only therefore be partially standardized, and the general profile of scavenging activity can hardly be anticipated, especially since most information concerning the environment is usually presumed indirectly: for example, the density of animal colonization in a specific area is usually estimated in correlation with the number of human inhabitants. However, the precise number of individuals and the specific species are often incompletely known. Another limit consists in the few existing geographical studies. Most of them deal with research conducted in specific geographic areas of North America, Europe, and Australia, and therefore their results are valid only for scavenging activity occurring within those areas and do not cover the entire geographical variability which may be encountered in forensic practice.

At the moment, very few experimental studies deal with the scavenging and scattering phenomenon, and most of the information derives from empirical observations, which, however, have contributed to define initial general characteristics of animal attack and the effects on the different steps of anthropological analysis.

Search and Recovery

Scavenging is usually followed by scattering: animals disarticulate the bone segments and usually transport them far away from the deposition site, with consequent difficulties for the phases of search and recovery. This means that with time the number of bones which may be found progressively decreases, whereas the area which should be

investigated increases. In addition, if operators presume that the remains have been scavenged, then the entire strategy of search should be adequately modified, in order to perform an efficient exploration of the area. Knowledge of precise patterns of scattering would therefore improve the manner of searching for dispersed human remains. For animals, the removal of bone segments is mainly aimed at reducing competition between different species and feeding the young: scattering is often coupled with the accumulation of remains, usually close to the dens of the specific scavenging animal; rodents, especially porcupines, are considered the most active accumulators. Every search procedure in case of scavenged remains should, therefore, also focus on dens and burrows of animals. Small bones and bone fragments may be eaten only to be later regurgitated or deposited with defecation. Hair, teeth, fingers, and small bones found in animal feces have been reported. Analysis of animal scat found in the area of scattering is important, since it may lead to the identification of the type of animal present in the area and to the detection of small bone or tooth fragments pertaining to the remains. For example, bone is more highly fragmented in small animals' scat, probably because of the limited dimension of their mouths. Felids have scats with a larger amount of bone mass, but contain fewer and greater fragments than dogs because of the bone-crushing profile of dogs' dentition. In addition, stomach digestion in dogs is more destructive, and this causes a deep modification of swallowed fragments. These are the first indications which may derive from the recent application of forensic scatology, and which show that the assessment of the scavenged and scattered body requires also a thorough analysis from a zoological point of view.

In addition, one should always consider that scavengers also come from above: vultures may attack corpses, and therefore spread human remains sometimes very far away from their point of origin. It is known that vultures can skeletonize a corpse in a short time, as seen during funeral rituals in different cultures which require the corpse to be exposed ('aerial burial'). Scattering distances of specific species are sometimes reported by authors, although there is a high variability due to the superimposition of other taphonomic factors such as the movement of skeletal remains due to sedimentation, rains, or other environmental or geological factors. In addition, scattering distance is related to weight and size of disarticulated remains, and to the strength of the scavenger as well.

Literature reports that the cranium is usually the most frequent anatomical area found in cases of scavenged remains; however, this may be due to the fact that it is easier to find compared to smaller bones such as vertebrae or phalanges. Different authors report incomplete/broken skulls showing signs of tooth marks and destruction, especially in cases of extensive head trauma existing before death, and Rodriguez has shown that medium-sized dogs can transport human skulls.

Generally, bones of the upper extremity are recovered less frequently than those of the lower extremity (50% of recovery rate for scapula, to a low of 25% for the clavicle, while those of the lower extremity range from a high of 65% for the femur to a low of 42% for the tibia). Bones of the axial skeleton are recovered between 74% and 61% of the time.

The positioning of scattered remains may be useful for reconstructing the manner of scavenging: global positioning

systems and other methods of mapping bone remains have a relevant role. These attempts may bring about relevant information for the reconstruction of a unique scattering profile, which may help in the differential diagnosis with other events that may have caused the spreading of bones, such as dismemberment.

Postmortem Interval Estimation

Scavenging is a natural phenomenon which has repercussions not only on the survival and consequent search and retrieval of human remains, but also on the stage of decomposition of the cadaver and, therefore, time since death evaluation; several authors state that a reliable estimation of postmortem interval (PMI) by evaluation of the decomposition process should always consider the possible scavenging activity by animals, since it may radically influence the trend of skeletonization of human remains. However, scavenging is not a physical effect such as temperature and weather, in general, which can be predicted, although with a large error; it has to do with animal behavior, which is hard to foresee. The first question concerns when exactly scavenging begins: relevant literature only gives partial information, since scavenged corpses are usually found after considerable time after death and the onset of scavenging cannot be reconstructed with precision. In cases of domestic pets, different authors state that the attack begins when food supplies are finished, although this indication is scarcely useful for predicting exactly when the scavenging lesions were produced. In addition, different case reports have shown that domestic pets may attack the corpse even when their food supplies are intact. In conclusion, the motivation of the animal is of the utmost importance, and although it is usually hunger, the precise dynamics concerning the decision to scavenge are not completely known.

The second question concerns how long scavenging lasts, and whether it is directly related with time. Different studies have observed that there is no precise correlation between scavenging and PMI and that scavenging is not a linear process and does not develop with a constant velocity. In addition, literature provides different indications concerning the general velocity with which each animal destroys a body: Willey and Snyder, for example, report that five adult wolves in an outdoor environment can consume a large deer weighing 55–73 kg in 4–7 days. This information gives a general idea concerning the velocity of the attack by a specific animal, but cannot be used to estimate PMI, since too many variables must be taken into account: for example, five wolves can consume a deer in 4–7 days, but what about one wolf? And are they likely to attack a human body in the same way as the deer? In addition, such general indications derive from case reports which are not standardized and cannot be used as a reference for other conditions, or even for other animals: for instance, information concerning how wolves attack should not be used to evaluate scavenging by dogs.

Authors have also observed that several variables may influence the scavenging process, such as rigor and freezing, in the early postmortem period. Another variable which may influence the time of scavenging is body characteristics: for example, clothing has proved to limit the attack by rodents,

but not by domestic dogs. In addition, probably the cause of death may have a large influence on scavenging, although very limited information is available: invasive trauma and a drug-related death may accelerate scavenging.

Finally, climatic variables are important as well; the few experimental studies performed show that scavenging may greatly influence decomposition during cold seasons, whereas in summer, when the body skeletonizes considerably earlier, the effects of scavenging are less pronounced.

PMI correlation with scavenging activity is an area of interest where information is still mainly anecdotal, and there is some disagreement among authors. This is further complicated by disagreement among authors: Wiley and Snyder, for example, suggest that it is difficult to correlate scavenging activity with time since death; on the other hand, Morse states that the amount of animal damage and the number of bones removed from the remains is directly correlated to the time of deposition. However, one should consider that not all bones are likely to be removed and transferred away from the original deposition site in the same manner. Ribs and vertebrae are likely to remain closest to the original place, as shown also by the few experimental studies actually available. In addition, degree of decomposition may produce relevant modifications of scattering, since it is usually more marked when the body is attacked early in the postmortem phase, when the soft tissues still hold together skeletal areas and relatively large segments of the skeleton can be easily removed, whereas when the corpse is skeletonized, bones around the specific one scavenged by the animal will be left in the original position. In addition, one should also consider that scavenging is often a discontinuous activity, which begins, may be abandoned, and initiated again according to the specific behavior of the animal and environmental variables.

Every attempt at standardizing a phenomenon must necessarily pass through a classification; Haglund suggests a classification for the evaluation of scattered remains called WDH (after William D. Haglund), where stage 0 represents the removal of soft tissue with no disarticulation; stage 1 the destruction of the ventral thorax characterized by absence of the sternum and damage to distal ribs, accompanied by evisceration and removal of one or both upper extremities, including scapulae and partial or complete removal of clavicles; stage 2 fully or partially separated and removed lower extremities; and stage 3 nearly complete disarticulation with only segments of vertebral column articulated. In stage 4, total disarticulation and scattering is usually observed, with only the cranium and assorted skeletal elements or fragments recovered. The original classification was made according to dog scavenging, but other animals disarticulate bodies in a similar manner, and this suggests that probably the dynamics of disarticulation are greatly influenced by anatomical factors also such as the intrinsic properties of bones and joint attachments.

If the dynamics of dismemberment of specific animals are similar, the same cannot be said for other parameters, such as the distance of scattering, which is strongly influenced by the size and strength of the involved species: Knight reports that foxes can drag body parts away to a distance of at least 3 km. In addition, the distance of scattering is influenced by ecological factors and soil characteristics.

Assessment of Lesions and Cause of Death

Animal scavenging usually occurs when bone surface is still covered with soft tissues; therefore, lesions due to animal scavenging usually display perimortem characteristics (though some authors automatically and erroneously classify them as postmortem-type lesions). This necessarily brings about relevant limits concerning the differential diagnosis between a lesion due to scavenging and one caused by some sort of trauma correlated to the cause of death. In addition, scavenging and trauma may be strictly related: for example, it has already been mentioned that crania affected by blunt trauma are more prone to be attacked by animals. Different authors report that scavenging may occur in areas affected by lesions, but that it is not more probable than in other areas. Blau and Ubelaker describe a case of a gunshot wound affected by scavenging signs. Quatrehomme and Iscan state that animal lesions may be confused with blunt and sharp force trauma or gunshot wounds, but postmortem activity usually does not result in beveling, or radiating or concentric fractures. Surprisingly, although literature extensively deals with scavenging dynamics, very little is known concerning whether its signs may actually disguise a lesion.

Literature has focused on specific characteristics of scavenging, especially those which concern rodents and carnivores. Gnawing usually proceeds from the cancellous articular ends of long bones (e.g., subadult epiphyses are particularly vulnerable). Rodent tooth marks on bone surfaces have been described by different authors as channels or striae, straight parallel grooves which are flat bottomed. A characteristic of gnawed cross sections of long bone shafts is their uniform pitch, extending from the outer to inner surfaces, whereas damage from carnivores is less regular and often rounded without uniform pitch from the inner to the outer surface. However, distinct parallel striae are not always detectable, since the morphology of lesions depends on the general characteristics of the bone: in cancellous bone or small long bones such as metacarpals, metatarsals, and phalanges, where the cortical component is extremely thin, such striae may be absent. In addition, shape of the striae depends on the manner of gnawing, and therefore may be totally disorganized.

Haynes and Binford recognized four characteristic types of carnivore tooth marks: punctures, pits, scoring, and furrows. Punctures are produced when bone collapses under a tooth and are recognizable as oval penetrations through the cortex, usually where the bone surface is thinner; they may be caused both by canine and carnassial teeth. Pits are indentations caused by the tips of the teeth as the animal bites down and occur when the strength is insufficient to penetrate the bone. Scoring is caused by teeth slipping and dragging over the compact bone, usually oriented transversally to the long axis of the bone. Furrows are caused by repeated jaw action of either canine or carnassial teeth, and may lead to the removal of cancellous bone and licking out its content from open shafts (Figures 1–4).

In specific geographic contexts, the analysis of scavenging involves signs left by other less common species: bears, for example, are more likely to break open the shafts of long bones and carry off or consume portions of the upper limb and axillary skeleton, and leave bones of the lower extremities.

Figure 1 Example of gnawing.

Figure 2 Crushing in a rib due to wild boar activity.

Figure 3 Punctures caused by teeth of carnivores.

A relevant point of discussion concerns not only the differential diagnosis between traumatic lesions produced before death and animal activity, but also between lesions caused by different animals: for example, Miller states that the incisors of canids such as coyotes (*Canis* sp. *C. latrans*) and wolves (*Canis* sp. *C. lupus*) can cause hollow grooves that may mimic the gnawing marks of rodents when they gnaw with their incisors transverse to the longitudinal axis of long bones. A classification of lesions according to different origins (rodent or carnivore) has been proposed as well: rodents usually produce

Figure 4 Furrows on the bone surface.

tight and circumscribed defects, with relatively smooth or crenulated margins, without damage of the area beyond the margins; carnivores instead produce irregular lesions in shape and margins, and cause scratching of the area beyond the margins.

Another issue is whether scavenging may hide preexisting lesions. The few experimental studies actually performed on blunt trauma show that scavenging may cause a displacement of the bone fragments, with a decrease of the observer's ability to recognize the signs of trauma.

However, although animal activity is supposed to produce lesions, the lack of signs does not mean that the body was not scavenged: for example, vultures may leave very slight signs of their attack, which may be referred to other taphonomical causes (such as weather and environmental modifications), or even remain undetected.

Finally, one should consider that scavenging, though more frequently associated with a terrestrial environment, is a well-known phenomenon also in the aquatic context, where freshwater crustaceans are the main scavenging species; they cause limited and superficial skin lesions of variable shape. Large-sized animals, on the other hand, can produce relevant modifications, with loss of skin, muscle, and bone tissues.

History of Forensic Anthropology

S Black, University of Dundee, Dundee, UK

© 2013 Elsevier Ltd. All rights reserved.

The history of a subject such as forensic anthropology can be relayed in many ways and with alternative focus depending upon where the narrator chooses to begin the story and which stream they choose to emphasize. For example, it may be told simply through a chronology of influential cases that illustrate the first of their kind, the most remarkable, biggest, most controversial, unsolved, or perhaps the most convoluted investigation. It may be told through a biography of the practitioners – characters who, for a variety of reasons, have shaped and molded the discipline (or indeed its precursors) and become its accredited pioneers or even blackguards. This definition holds equally true for an organization or an institution, where the combination of people, place, and time may result in advancements through leadership or event. These events may in themselves form the basis of a history, and they may relate not only to important physical phenomena such as mass disasters, but also to changes in approach and perception of the discipline, perhaps resulting in a change to legislation or accreditation. Indeed the event may even relate to a pivotal publication. The reality, of course, is that an accurate historical account of a discipline, such as forensic anthropology, combines and interweaves all of these and it is how authors choose to relay those facts, in their own personal opinion, that lays down a series of narratives, all of which will have truth but will tell the story from a slightly different perspective. Such is the way with history; at the point of writing, it is merely a chronicle of a person's viewpoint based on how they interpret the evidence and how they choose it to be portrayed.

Perhaps, the easiest way to address a history is with consideration of 'firsts' – the first case reported or the first person to do something, but this may rely on the definition one uses of the subject at a time when there was no such recognized or named discipline. Must one then define the discipline to be able to identify a time of its birth? Doing that opens up great debate, as it is well recognized that anatomy, anthropology, and, subsequently, physical anthropology are the natural predecessors of forensic anthropology. Yet, if one chooses a case that illustrates for the first time that the recognizable subject was used in a court of law (as is the true meaning of 'forensic'), then the history starts quite late and takes little cognizance of the giants upon whose shoulders forensic anthropology truly stands.

Human anatomy has a history that dates back to the founders of modern medicine – Galen (AD 130–201) and Hippocrates (460–370 BC). But all anatomy prior to 1539 was superseded by a publication from Andreas Vesalius (1514–64), a Flemish anatomist, who challenged Galen and Hippocrates through his hugely influential *De humani corporis fabrica* 1539 (*On the Workings of the Human Body*). This text formed the basis of all modern studies in human anatomy and, one could argue, paved the way for anthropology and its successors. Physical anthropology as a science began to gain popularity during the sixteenth and nineteenth centuries

with Johann Friedrich Blumenbach (1752–1840), a German physician, anatomist, and physiologist, who was widely regarded as the founder of the subject. His treatise on the racial classification of man was published more than 80 years before Darwin's 'Origin of species.' Paul Broca (1824–80), a French physician and anatomist of significant renown, was unquestionably one of the most influential supporters of the science of physical anthropology, and he founded the Anthropological Society of Paris in 1859. It was his understanding of anatomy, however, that led to his most well-known research into speech areas of the brain, comparative primate anatomy, and cranial anthropology.

If one is going to find the first fully documented case in which physical anthropology assisted the court (and hence turned it into forensic anthropology), then that is most likely to be attributed to anatomists at Harvard University in North America in 1849, although it is distinctly possible that anatomists will have assisted investigators prior to that time in matters pertaining to the human form. Dr John Webster was accused of the murder of George Packman following dispute over a bad debt. Burned remains were located in a vault under the office of Dr Webster and the identity of these was attributed to Packman following analysis by Prof. Jeffries Wyman (anatomist) and Oliver Wendell Holmes (Dean of the Medical College). Webster was found guilty and hanged in 1850. There may well have been other legal cases in history prior to this which could carry the moniker of being the first time that anthropology or anatomy was used in the courts, but there is little merit in such debate as it serves only to set a start date for the recognition of the discipline recognized today; it is probably sufficient to accept that it can be traced to at least the 1850s. However, it is known for certain that the Harvard anatomists were the first to offer classes and training in physical anthropology in the 1890s.

A case of notoriety within the United Kingdom and the first to be attributed to the discipline in that country (although again it was via anatomists) was the murder of Isabella Ruxton and her housemaid Mary Jane Rogerson. Both were murdered by Isabella's common-law husband, Dr Buck Ruxton, who was a GP of Indian birth and worked in Lancaster in the north of England. He had dismembered the remains with expertise but had been careless in their distribution (a feature that was to be replicated over 70 years later with the murder, dismemberment, and deposition of the remains of Jeffrey Howe). A team led by Prof. John Glaister, a forensic pathologist at the University of Glasgow, and Prof. James Brash, an anatomist from the University of Edinburgh, pieced together the remains and, through superimposition of the skull onto photographs, confirmed the identities of the two individuals. Ruxton was found guilty and hanged in Manchester in 1936. The similarities between the Ruxton and Howe cases are worthy of consideration and confirm the well-understood principle that basic patterns of behavior can be learned from studying case histories, which can then be used to inform current investigations.

From the formative years of forensic anthropology, it is perhaps difficult to accredit single individuals as the undisputed pioneers of the discipline without causing offense, but undeniably one can include Blumenbach (1752–1840), Broca (1824–80), Virchow (1821–1902), Dwight (1843–1911), Bertillon (1853–1914), Boas (1858–1942), Dorsey (1868–1931), Hrdlicka (1869–1943), and Hooton (1887–1954). The start of the Second World War saw a change in the discipline as it started to mature and become better recognized by law enforcement agencies for its capabilities. Throughout that time, reputations were made either through publications or single cases that would hit the headlines. In 1939, the modern era of forensic anthropology started to emerge with the publication of Wilton Krogman's 'Guide to the Identification of Skeletal Material,' and he followed this sometime later in 1962 with the seminal text 'The Human Skeleton in Forensic Medicine.' In the era up to the 1960s, the work of Trotter (1889–1991), Todd (1895–1938), Stewart (1901–97), Krogman (1903–87), Snow (1910–67), Angel (1915–96), McKern (1920–74), Kerley (1924–98), and many others too numerous to list should also be recognized. Snow, Trotter, Stewart, and McKern are renowned as pioneers in the identification of military war dead, both as a result of the Second World War and following repatriation of personnel following the Korean War. This time saw a change in the utility of forensic anthropology, where the analysis of skeletal remains, in a time prior to DNA analysis, was the most reliable means of facilitating identification and repatriation of war dead.

There is little doubt that the United States has led the early stages of the recognizable discipline of forensic anthropology, and one of the clear indicators of this is the early recognition of the importance of professionalization of the discipline and the need to identify those who are competent to practice. In 1972, the Physical Anthropology section of the American Academy of Forensic Sciences met for the first time under the direction of Ellis Kerley and Clyde Snow. Five years later, the American Board of Forensic Anthropology was created, and, at the time of writing, this consisted of 88 certified diplomates, 65 of whom are current practitioners. The history of forensic anthropology within the United States is well documented, but the history of the discipline is also influenced by what goes on around the rest of the world.

Part one of the text 'Handbook of Forensic Anthropology and Archaeology' edited by Blau and Ubelaker offers a summary of the history of the discipline from countries including the United Kingdom, Italy, France, Spain, South America, the United States, Canada, Australia, and Indonesia. Kranioti's paper adds some information from Ireland, Sweden, Norway, Denmark, Finland, Germany, Austria, Netherlands, Hungary, Russia, Portugal, the Balkan states, Turkey, Greece, and Cyprus. What is clear from these communications is the variety of origins, practitioner types, case type, and etiology of the discipline in each of these countries. The reasons that a detailed history of forensic anthropology outwith the United States has not really been attempted in any great depth are perhaps its complexity and nonconformity. Therefore, it is perhaps easier to look at temporal and geographical events rather than single cases or practitioners to establish what has occurred globally for this discipline.

Special mention is necessary for the development of forensic anthropology in Latin America. In 1984, Clyde Snow led a

team from the American Association for the Advancement of Science into Argentina to assess the situation regarding the investigation of victims of political violence. With probably close to half a million missing from Guatemala, Argentina, El Salvador, Peru, Chile, and Colombia, it was clear that the value of forensic anthropology could be put to good use in the identification of those recovered from graves associated with these crimes. The Argentinean Forensic Team was set up in 1984, followed by a Chilean team in 1989, a Guatemalan team in 1992, and finally a Peruvian team in 2001. Not only did these highly experienced groups operate within their own territories, but it soon became clear that their experience and expertise would be called for all over the world, and nowhere more so than in the Balkan states during the wars of the 1980s and 1990s.

Figures vary but nearly 100 000 people lost their lives in the armed Bosnian conflict between 1992 and 1995. International forensic teams under the guidance of the United Nations collected evidence, exhumed remains, and undertook identification of the deceased in preparation for an anticipated International Criminal Tribunal. In 1994, the genocide of over 800 000 in the small east African country of Rwanda took the world by surprise, as it took place over the space of only 100 days. Forensic anthropologists were called to assist with the recovery and identification of the remains for the purposes of the International Criminal Tribunal for Rwanda. Then, several thousand more deaths were recorded in Kosovo, which terminated with the North Atlantic Treaty Organization (NATO) bombings between 24 March and 11 June 1999. The experience of the forensic teams in Bosnia and Rwanda was critical but gratis teams from other countries were called to assist with Kosovo investigation as neither the Bosnian nor the Rwandan investigations were completed by the time forensic assistance was required in Kosovo.

So, while one could argue that throughout the 1990s, in particular, as forensic anthropology was at its height, there was an almost unprecedented demand for the expertise of these professionals, with the United States (and Latin America) as the only prime source of practitioners, it was not surprising that American anthropologists took a leading role in the collation and interpretation of evidence of war crimes. However, a protracted deployment that demands large number of practitioners faces a crisis when operations such as these begin to be wound up and services are no longer required. The wars with Iraq (Operation Desert Storm 1990–91), particularly the second of those (Operation Iraqi Freedom 2003–10), required investigation of mass graves identified following the killings of Saddam Hussein's regime but not on the same scale as had been seen in the Balkans and Rwanda.

Throughout the 1990s, academic institutions responded to the global demand for forensic anthropologists by offering degree courses at many credible, and perhaps not so credible, institutions. The media had latched onto the work of the discipline, and novels, television series, and movies started to portray the work in a light that encouraged more and more school leavers to study at institutions of further education. But it was clear that without the conflict and the demand, the likelihood of employment would be slim, and a large number of courses started to dwindle with the turn of the new millennium.

However, there was yet another turn of events that saw the discipline raise its profile not just in relation to single cases or war crime investigation but in response to disaster victim identification (DVI). The terrorist attacks on the World Trade Centre in 2001, the Bali bombings in 2002 and 2005, the tsunami of 2004, London bombings of 2005, and the Australian bush fires of 2009 all required assistance from forensic anthropologists who became integral members of the DVI teams, and the discipline was incorporated into the DVI training programs and instructional texts. Particularly, those forensic anthropologists who were anatomically trained found that their services were in demand through their ability to identify not only the skeletal remains but also the soft tissue structures, and this made their involvement in early triage operations indispensable.

In 2003, forensic anthropologists in Europe set up the Forensic Anthropology Society of Europe as an official subdivision of the International Academy of Legal Medicine. One of the main objectives of this society was 'to encourage the study of, to promote the practice of, to establish and enhance the standards for forensic anthropology and to promote training and create a board of trained professionals.' According to its website, the society has 47 listed members and perhaps as many again who are not listed.

In 2010, the British Association for Forensic Anthropology was set up under the umbrella of the British Association for Human Identification. With over 80 people attending its inaugural meeting, this group aims to promote and develop the discipline within the United Kingdom and prepare practitioners for accreditation through processes agreed with the office of the Forensic Regulator, which is a part of the Home Office, and in alliance with the Royal Anthropological Institute as its professional and accrediting body.

Forensic anthropology has not yet fully matured as a discipline across the world. Some areas are clearly in advance of others, as they address standardization of practices, issues of competency among practitioners, and admissibility of evidence to the courts. It is clear though that the story has not yet come to a conclusion and indeed the discipline does not as yet seem to have reached its own zenith, as new and exciting avenues of investigation seem to be migrating to the discipline. For example, the science of taphonomy, evaluation of age in the living, and identification of individuals from images are all skills being offered by specializing anthropologists. Despite the almost increasing multiplicity of the discipline, it is clear that

forensic anthropology is a recognized field of expert evidence that is highly relevant to the modern world and deserves its newly acquired seat at the table of decision makers.

Forensic Anthropology: An Introduction

C Cattaneo, Università degli Studi di Milano, Milano, Italy

© 2013 Elsevier Ltd. All rights reserved.

Today the adjective 'forensic' seems to be applicable to almost any discipline. So in the past decades, the evolution of 'saprophytic' disciplines (feeding on original ones such as pathology, entomology, botany, archeology, and many others) into forensic ones, that is, forensic pathology, forensic entomology, and so on has been seen. The same is true for anthropology, a very vast domain. Because it studies humans also in the context of culture and behavior, anthropology is sometimes classed as a social science. Traditionally, it has two main branches (according to some academic schools even more), which can be identified as cultural and physical anthropology: the first is related to the more social and artistic realms of man, whereas the second to the more physical ones. According to the American Association of Physical Anthropology, this discipline is defined as a biological science that deals with the adaptations, variability, and evolution of human beings and their living and fossil relatives. Physical anthropology is therefore 'the' anthropology that has been adopted by forensics at the moment: but one can expect that in the future, many aspects of cultural anthropology may merge with criminal anthropology, and perhaps even criminology.

Forensic anthropology (FA) has been defined as the application of physical anthropology, generally intended as human osteology, to the forensic scenario. The following paragraphs therefore refer to what is traditionally known as FA and the new developing fields.

Before discussing what anthropologists do in the forensic scenario, it is worthwhile to spend a few words on who the anthropologist is. Certainly, the anthropologist is not superimposable to the pathologist. Even in cases of skeletal remains, a pathologist must always be involved as he or she is the only specialist (technically and bureaucratically) who can diagnose and certify the cause of death. Nonetheless, forensic pathologists usually have very little training in osteology and anthropology; therefore, the anthropologist is a fundamental figure for extrapolating from human remains information, which is written in the skeleton and needs specialized training in order to be deciphered appropriately (this goes beyond standard medical forensic training); for example, establishing age from the pubic symphysis or distinguishing a perimortem from a postmortem fracture. For what concerns training and certification, this is an even more difficult issue, as for many disciplines of the forensic realm. Some countries, such as the United States, have certified boards with specific prerequisites (an examination, a masters course, a PhD, and casework), others (most European Countries) have none and FA is dealt with by both pathologists and physical anthropologists. Some countries have postgraduate training in FA (e.g., UK, Italy, and USA) and, again, some do not. Therefore, depending on the country or even on the single situation, one may encounter different training – if at all – of the forensic anthropologist. Risks are that physical anthropologists with no experience in forensics will take on cases and that pathologists with no experience in

osteology will deal with bones. Furthermore, the lack of certification or of some sort of 'control' over who can actually practice this 'profession' opens the field to many self-made men with inappropriate training. This, however, is a problem frequently occurring in other disciplines adopted by the forensic world, such as botany, geology, entomology, and so on.

Going back to the more technical discussion on FA, one can say that in the traditional scenario, the anthropologist comes in when 'extreme' states of decomposition of the body are present (skeletonization and severe charring) and bone and teeth become the only tissues available (although this discipline can be useful also in cases of extremely putrefied cadavers where soft tissues are no longer informative and the study of the underlying calcified tissues may yield more information).

Though physical anthropology has always included the study of man and his diversity *in toto*, even with respect to skin pigmentation or blood type for example, the forensic version has adopted the subsections closest to archeology, in other words, everything that implies the study of human skeletal remains. The discipline of anthropology, therefore, begins 'on site,' following the closest archeological tradition. Forensic archeology is a very close cousin, according to some even a subsection of FA, and contemplates the application of archeology to the forensic context for the search and proper recovery of human remains. The forensic anthropologist therefore usually has some competence in recovering human skeletal remains underground or on the surface.

Before studying the human remains themselves, these in fact have to be properly recovered and sometimes even need to be found. Mostly, searching for human remains is the scenario of the forensic archeologist: he or she must have the proper experience to know how to look for a criminal burial site – and know whether to use aerial photography, geophysics, or other means. When the remains, in particular, skeletal remains, are found, the scene of crime team should include an anthropologist who has appropriate training for recognizing and recovering bones, verifying if any are missing and so on. Another example of the role of the anthropologist at the scene of crime is in the case of burnt and charred human remains, when all that is left of the entire body are small fragments of bone. In these cases, meticulous sieving through the remains (in a burnt car for example) performed on behalf of an expert in osteology may help retrieve much more osseous material, and therefore, more information concerning identity, cause of death, and other precious data: it should always be kept in mind that in fact, in the case of human remains, the only lesion present may be on the smallest bone of the hand, such as a phalanx, and that it is therefore crucial to recover every single piece of bone.

Before dealing with the actual study of the bones as one or more individuals, in skeletonized cases, anthropology is the discipline with the tools for verifying whether a bunch of bones are of forensic interest, that is, if they are human', and, if so, recent. According to the morphological study of such

remains (and at times histological), the anthropologist will verify whether the bones are human'. Human bones, when intact, are generally distinguishable from nonhuman ones due to their specific morphology. However, in the case of small fragments or very degraded pieces of bone, shape and size are frequently of little help. DNA tests can of course be performed but quicker and less costly methods exist in anthropology which can easily lead to a diagnosis of human vs. non-human. Once the anthropologist has decided for a human origin, another preliminary task to the actual study of human remains must be to verify whether they are ancient or recent and what the postmortem interval is. If such a diagnosis is relatively simple when soft tissues are still present, even though decomposed, through the study of the level of degradation (e.g., Accumulated Degree Days) or through entomological analyses, everything becomes more complicated with complete skeletonization. A clean skeleton may be 5-, 10-, or 100-years-old and look the same – at times only sophisticated chemical tests can do the job when no macroscopic or microscopic method will give a reliable time since death estimation. Anthropologists have in fact recently become more and more acquainted with radiocarbon and other isotope tests and with the many laboratories across the USA and Europe who actually perform them.

The most traditional task of the anthropologist or osteologist is, however, what comes next – building the biological profile. For centuries, anthropologists (previously with calipers, nowadays also with more complex technology) have been experts at detecting and describing human diversity on bone, and therefore, at sexing, aging, determining ancestry, stature, and to a certain extent, pathology of the skeleton. Thus, the 'identikit' of the skeleton of a victim will be built on the basis of bone morphology and metrics. In the end, a face can even be suggested if the anthropologist goes as far as performing what is known as facial reconstruction or approximation. This is a technique by which according to specific anatomical landmarks, soft tissues are applied step-by-step onto the cranium (or a cast) in order to provide a face, which may look like the person when he or she was alive. At this point, the anthropologist has set the basis for identifying the skeletonized victim of a murder or simply someone who died and whose body decomposed with no ID. The problem of unidentified human remains is becoming an increasing social, ethical, and juridical problem, particularly given the increase of illegal immigration in many countries; forensic anthropologists have the expertise to help solve such cases.

Once the biological profile is confronted with missing persons, a possible ID may come up; in other words, there is an idea of who the skeleton may have belonged to in life, then it is necessary to go on to the next step, personal identification. Personal or positive identification is usually performed by odontologists, fingerprint experts, and DNA specialists. It consists of comparing biological antemortem and postmortem data in order to verify whether a definite match can be made. However, sometimes, when such antemortem data is missing (e.g., no dental records exist, no family or DNA antemortem materials such as toothbrushes can be found, and the person doesn't have a criminal record, and therefore, no registered fingerprints), bone morphology may again be useful for identification, and therefore, anthropology (along with radiology) may provide positive identification. Every bone has a peculiar

shape and has specific identification potential. Frontal sinus shape, for example, can be extremely useful for identifying remains when an antemortem X-ray of the cranium exists. The method of comparison of the antemortem and postmortem shapes of this part of the frontal bone has even been standardized but virtually all bones have sufficient identification potential. Sometimes no antemortem medical records at all exist, and all that is left is a photograph of the person whom one thinks the remains belong. In these cases, craniofacial comparison or superimposition can be attempted although it should be used with great caution, and according to some authors only to exclude identity.

As previously mentioned, the anthropologist can aid the pathologist in looking for and interpreting signs of bone trauma, especially in distinguishing genuine trauma from bone lesions deriving from weathering or postmortem artifacts, in other words from taphonomical events. This can be done only by experts properly trained in the effects of animals and environment on bone. An important issue is also that of identifying the correct timing of a bone fracture: was it produced at the time of death, before, or after? Anthropologists for these purposes have had to coin a new terminology. Contrary to pathologists who can usually tell from well-preserved soft tissues whether a lesion was produced before or after death, anthropologists are limited to antemortem, perimortem, and postmortem diagnoses, where antemortem represents a time necessary to visualize signs of bone healing (generally weeks before death), postmortem implies a time long enough after death to have allowed the bone to lose all elastic properties so that a break in the bone will appear 'old,' and perimortem includes any fracture produced at a point where the bone tissue still had elastic properties, which means, variably, some time before or after death. At this moment, there is no way of being certain, contrary to the situation with soft tissue, that a bone fracture was vital.

Anthropology usually also deals with the biomechanics of bone (how bone breaks) in order to extrapolate the dynamics behind a bone fracture and with the more frequent manifestations of trauma on bone, namely blunt force, sharp force, and gunshot injury. Anthropologists have started to concentrate not only on the appearance of these injuries on bone, but also on the survival of residues, which may help orient toward the type of instrument used. For other types of exogenous deaths, such as mechanical asphyxias (e.g. drowning and strangulation) and toxicological deaths, osteology collaborates with other subdisciplines: in the first case, for example, to verify the presence of minute microorganisms such as diatoms in bone in order to be able to verify if we are in front of a case of drowning; in the second, if there are actual toxicological substances surviving in the bone that can reveal something on cause of death, which, as previously mentioned, should be dealt with by the forensic pathologist.

Then there are the newer trends of FA. These consist of the extension of FA to the study of the morphology of body and face of the living – an area which has more of a tradition in Europe, particularly in Germany and in the East. Many more issues such as identification of individuals filmed by videosurveillance systems from body shape and facial physiognomy are becoming important in the forensic scenario. For example, videosurveillance has become extremely common in many

public and private places across most developed countries, from banks to airports. Thus, a common question that judges are beginning to ask is whether it is possible to identify a suspect as someone committing a crime on a photograph or on a video. As a consequence, identification experts have to deal with determining stature and facial similarities from Video Home System (VHS) or digital supports, a task which is extremely difficult also because of the lack of research in this area and of standards and tested protocols. The same can be said for juvenile pornography. It has now been verified that the external appearance of genitals cannot be used for determining whether the objects of pornography are under age or not from photographs. Research is looking elsewhere for an answer, for example, toward facial morphology and proportions, another area of interest for anthropology in the forensic scenario. These and other new developments will probably require the integration of such topics in FA courses in order to prepare future scientists for novel fields of research and court work.

Regardless of what specific area of anthropology one is dealing with, the forensic expert, even in this field, must distinguish himself from anthropologists working in other contexts thanks to a forensic mentality, a *forma mentis*, which encompasses sustaining scientific theory and facts according to specific prerequisites and regulations (in this day and age, Daubert and Kumho, for example, requesting that methods be accepted by the scientific community, that they have known errors, etc.). Anthropology cannot be conceived as forensic unless it is applied according to these rules which are fundamental in order to sustain results and hypotheses in court.

Finally FA has strong links with several disciplines related to the natural sciences which it cannot be separated from, especially in this period in which there is a growing conscience of how many subjects may be pertinent to a single scene of crime or a single body. For example, frequently the anthropologist deals with remains covered in soil, insects, and foliage. Before the osteologist even begins to clean the bone, the question must arise as to what should be saved – and how important it is – of all the ‘dirt’ that needs to be washed off before the bone can be studied. Surely it contains elements of interest from a geological, botanical, and entomological point of view

(to name but a few). Thus the osteologist needs to consult with the natural scientists before even beginning his or her work. During identification procedures, the anthropologists frequently need to compare notes with DNA and dental experts. For example, in order to complete the biological profile, sometimes dental work can give important clues, and tips on sex and race in difficult cases can be given by DNA.

In conclusion, FA cannot be easily and simply defined. It has, however, great relevance both in the study of human remains and of the living.

Forensic Taphonomy

T Simmons and PA Cross, University of Central Lancashire, Preston, UK

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Accumulated degree days (ADD) The sum of the average daily temperatures where the body was found from the time of death until the discovery of the body. ADD is used in conjunction with TBS to estimate the postmortem interval.

Commingling When body or skeletal parts of different individuals have become mixed together at the time of death or postmortem.

Postmortem interval (PMI) The time that has elapsed since the individual died. PMI estimation is important in

identification of unknown individuals from missing person records as well as in establishing a range of dates when the individual likely died, which may be useful in eliminating or including suspects in a homicide investigation.

Total body score (TBS) An integer value assigned to a body by scoring three regions (head and neck, torso, and limbs) according to the appearance on a scale of decomposition. TBS is used in conjunction with ADD to estimate the postmortem interval.

Introduction

Forensic taphonomy is a rapidly developing field within forensic anthropology and forensic archeology. Research in forensic taphonomy encompasses refining estimates of time since death in various scenarios, differentiating peri- and postmortem trauma, identifying the effects of burning, understanding the directionality of impact in blunt force and projectile trauma in various skeletal elements, reassociating individuals commingled in secondary mass graves or explosions, weathering of bones and teeth, and an extended range of related topics.

Although taphonomy itself has a relatively long history in the paleontological and archeological literature, forensic taphonomy is a comparatively new discipline, developing in response to the demands of casework and to the various circumstances in which bodies are found.

History and Development of the Role of Taphonomy in Forensic Anthropology

Taphonomy roughly means the study of death assemblages and is said to refer to the laws of burial; the term itself was coined in 1940 by Efremov, who stated that taphonomy was the 'study of the transition, in all details, of organics from the biosphere into the lithosphere of the geological record.' Until relatively recently (the late 1980s), taphonomy was a term used predominantly within vertebrate paleontology, prehistoric archeozoology, and archeology. In 1997, Haglund and Sorg defined the goals of traditional taphonomy as the preservation, observation, or recovery of dead organisms; the reconstruction of their biology or ecology; and the reconstruction of the circumstances of their death. Taphonomy has featured prominently in paleontological and zooarcheological publications since the later three-quarters of the twentieth century. In 1927, Johannes Weigelt's published *Rezente Wirbeltierleichen und ihre paläobiologische Bedeutung*, which was unfortunately not translated into English, as *Vertebrate Carcasses and their Paleobiological Implications*, until 1989. This prescient book detailed Weigelt's observations on the decomposition of animal

carcasses on the coast of Texas and brought to light the role of insects, surface decomposition, carcass positioning in burial and partial burial contexts, sequences of disarticulation, and environmental significance among other topics. In 1981, Pat Shipman published an edited volume with a huge impact on prehistoric archeology and archeozoology entitled *Life History of a Fossil: an Introduction to Taphonomy and Paleoecology*, which introduced a wide variety of techniques for assessing taphonomic principles. Arguably, the first forensically relevant taphonomic publication in book format occurred in 1987 with Boddington, Garland, and Janaway's *Death, Decay and Reconstruction: Approaches to Archaeology and Forensic Science*; although it contained a chapter by W.M. Bass, it was primarily archeological in orientation and received little notice outside of the United Kingdom. Lyman's *Vertebrate Taphonomy*, published in 1994, brought together the current knowledge in the field, ranging from skeletal assemblage accumulation and dispersal to the diagenesis of bone itself. The traditional goals of taphonomy were emphasized, including reconstructing paleoenvironments, determining which factors cause differential destruction/attrition of bone, understanding selective transport of skeletal elements, discriminating human from non-human agents of bone modification, and reconstructing paleoenvironments.

Research in forensic taphonomy was spurred by the founding of the University of Tennessee, Knoxville's (UTK) Anthropological Research Facility (ARF) in 1981. Since 2000, the facility receives donations of approximately 100 bodies per year and the WM Bass Skeletal Collection, derived from the facility, now numbers around 700 skeletons. Although UTK staff and students have presented and published widely, the majority of publications emanating from the institution concern skeletal metrics rather than taphonomy itself. A paucity of publications from the ARF relating to decomposition have been forthcoming over the past 30 years of its existence; the best known are probably the earliest, for example, Rodriguez and Bass in 1987 and Mann et al. in 1990, and although the most recent publication by Vass in 2011 proposes formulae for calculating the postmortem interval (PMI), it presents no data from which these formulae are derived and no prior

publications from the ARF provide these data. In the twenty-first century's recent years, at least three other human decomposition facilities have been founded: Texas State University at San Marcos, Western Carolina University, and Sam Houston State University, TX.

1997 saw the publication of Haglund and Sorg's landmark edited volume, *Forensic Taphonomy: The Postmortem Fate of Human Remains*. The volume consisted primarily of case studies and dealt with decomposition in different environments, bone modification (including fire, trauma, trophy skulls, and scavenging), and the fate of remains in water (lacustrine, riverine, and maritime). Haglund and Sorg stated the goals of forensic taphonomy to be estimating time and circumstances since death; distinguishing postmortem conditions, which may confound human identification; determining cause and manner of death; identifying factors relating to skeletal element survival; reconstruction of events following death; collecting and analyzing data about context; discriminating post- from perimortem modification; and estimating the PMI. The techniques of forensic taphonomy included involving the application of archeological search and recovery techniques, the laboratory analysis of remains, and the understanding of soft tissue and bone modification and distribution. The 1997 publication was followed in 2002 by a second edited volume, *Advances in Forensic Taphonomy: Method, Theory, and Archaeological Perspectives*, which presented more diverse and international case studies with a greater emphasis on context. Further publications in 2008 included Tibbett and Carter's *Soil analysis in Forensic Taphonomy: Chemical and Biological Effects of Buried Human Remains* and Adams and Byrd's *Recovery, Analysis and Identification of Commingled Human Remains*.

Forensic taphonomic literature and research are concerned with documenting the changes to the body that occur postmortem from the earliest signs of autolysis to skeletonization, as well as the fate of skeletalized remains in disarticulation, transport, weathering, and so on.

Decomposition and Postmortem Change

The cessation of oxygenated blood flow to body tissues initiates the start of autolysis or 'self-digestion.' Autolytic changes can be seen microscopically shortly after death. These include mitochondrial swelling and calcification, dilated endoplasmic reticulum, aggregated cytoskeletal elements, and membrane disruption. The cell nucleus and mitochondria also exhibit condensed chromatin as a result of the fall in pH. Autolysis begins in the most metabolically active cells, which are more sensitive to oxygen depletion, such as the brain and heart muscle and those that contain a large quantity and diverse array of hydrolytic enzymes, such as the liver, pancreas, stomach, and intestines.

Macroscopic autolytic changes result from the leakage of hydrolytic enzymes into the intercellular spaces where cell junctions facilitate cell-to-cell adhesion. The breakdown of this intercellular adhesion results in the gross appearance of tissue friability and eventual liquefaction, and some of the notable postmortem changes such as skin slippage.

Autolytic activity creates an increasingly anaerobic environment which favors the rapid growth of bacteria that normally inhabit the body. The release of large amounts of breakdown

products provides nutrients for bacterial and fungal flora. The proliferation of microorganisms and their metabolic by-products results in the color, odor, and morphological changes characteristic of the putrefactive stage of decomposition.

Early Postmortem Changes

Early postmortem changes are often referred to as those that occur within 2 h of death. The changes include 'pallor,' a paleness of the skin on upper areas of the body seen in light-skinned individuals due to the loss of circulating oxygenated blood and the gravitational settling of blood to lower regions. Skeletal muscles relax during this period, including sphincter muscles, and this may cause early purging of fecal, urinary, or gastric contents.

Relaxation of the obicularis oculi muscles may expose the cornea to drying and this exhibits as a dark band running across the cornea, known as *tache noir sclerotique*. Postmortem autolytic changes within the retina, and to a lesser extent the lens, result in electrolytes diffusing into the vitreous body. Of particular interest, and the most studied, is the influx of potassium ions (K^+) into the vitreous humor. Owing to the isolation of the vitreous humor compared with blood or cerebrospinal fluid (CSF), levels of vitreous potassium are a favored area of study in estimating PMI.

Late Postmortem Changes

Late postmortem changes are often referred to as those that become observable from 2 to 4 h postmortem.

Livor mortis, also known as lividity or hypostasis, is the gravitational pooling of blood to lower dependant areas resulting in a red/purple coloration. Although livor mortis is commonly seen between 2 and 4 h postmortem, its onset may begin in the 'early' period, as little as 30 min postmortem. In the early period of livor mortis, the coloration is not 'fixed' and pressure of the skin can cause 'blanching.' During this period, changing the position of the body can result in resettling of the blood in newly dependant areas. After a period of time, the blood coagulates and livor mortis becomes fixed. Rigor mortis is a reversible postmortem stiffening of the muscles, beginning in the muscles of the face and jaw, and extending to the rest of the body as the postmortem period progresses. The onset of rigor mortis is dependent upon temperature and the metabolic status of the deceased and occurs concomitantly with early stage autolysis. The timing of the onset of rigor mortis is variable, but it normally begins 2–6 h postmortem and has extended over the body by 12 h postmortem. Rigidity can last for 24–82 h after which gradual resolution occurs, progressing in the same order as rigor mortis commenced. Algor mortis is the cooling of body after death as it equilibrates with ambient temperature. Normal body temperature (rectal) can vary between individuals, ranging from 34.2 to 37.6 °C with a mean of 36.9 °C. Rectal temperature is similar in value to that of the brain, lungs, and abdominal organs and is often referred to as 'deep central temperature.'

A number of factors can influence body temperature at time of death, including emotional stress, pathological febrile conditions, metabolic disorders, circulatory disorders, and exposure to extreme environmental temperatures. Further factors

influence the rate of cooling. These include body posture, body size, body fat, and presence of clothing.

Skin slippage occurs as a result of autolytic release of hydrolytic enzymes at the junction of the epidermis and dermis. This results in loosening and sloughing of the epidermis. This may be seen initially as the formation of vesicles or blisters. Fluid-filled vesicles known as 'bullae' can also form beneath the epidermis. Larger areas of skin may slough off and this can occur on any area of the body. Hair and nails will also be lost with the skin and where this occurs on the head, the whole scalp can slide off.

Color changes are indicative of putrefactive changes. They occur as a result of (1) the degradation of hemoglobin and (2) the formation of hydrogen sulfide (H_2S) within vessels and tissues by enteric bacteria. Greening of the lower abdomen may occur within a few hours of death. The cecum, in particular, has a large population of enteric bacteria and will produce a large quantity of hydrogen sulfide. This will react with hemoglobin and other heme-containing proteins (e.g., myoglobin) and produce a green coloration in the lower abdomen, which becomes widespread throughout body tissues. The greening of superficial blood vessels can give the appearance of 'marbling,' sometimes called suggillation.

Bloating occurs as a result of putrefactive gases becoming trapped within the body. In addition to hydrogen sulfide, a wide range of other gases are produced during the putrefactive stage. The trapped gases cause distension of the abdomen, and in males, the trapped gases can be forced into the scrotum via the inguinal canals, causing distension of the scrotum and penis. As gases build up within tissues, bloating can also be observed in the tissues of the face and neck.

Putrefaction results in a complex mixture of volatile gases produced from the breakdown of carbohydrates and proteins. Two notable products are putrescine and cadaverine, both products of protein breakdown. These products have the characteristic decomposition odor and are utilized by cadaver dogs in the search for human remains.

Insect Decomposers

The rate of autolysis and the rate of putrefaction resulting from microbiological activity are dependent primarily on temperature. Given time, autolytic and putrefactive changes will result in liquefaction of soft tissue.

The rate of decomposition of a body accessed by insects is rapidly increased, as larval masses can result in significant soft tissue loss in a short period of time. In a suitable environment, insects are attracted to a body within minutes, their activity being temperature-dependent also. The population of insects on a body will be particular to that specific environment, as well as to a given geographic area. Typically, blowflies (Diptera: Calliphoridae) will be attracted to the volatile gases emanating from the alimentary canal via natural orifices (e.g., mouth, nose, anus) and those produced by early stage putrefactive changes. Their larvae can form large masses feeding on soft tissue. Although beetles (Coleoptera) are commonly associated with remains in later stages of decomposition, some (e.g., Silphidae) are present on the body during early stage decomposition, as dipteran larval masses represent a food source for them.

Adipocere

Adipocere, also known as 'grave wax,' is a caseous material formed by the saponification of body fat. Adipocere may appear paste-like, be crumbly in texture, or may form a hard material depending upon the type of fatty acids involved and the chemical environment in which it is formed. Moist, anaerobic conditions favor the formation of adipocere but its appearance is not restricted to immersed remains. Any grave or terrestrial environment where adequate moisture is present can result in the formation of adipocere. In surface depositions, adipocere formation can occur in oxygen-deficient dependent areas where fat is in contact with moist ground. Adipocere is very persistent and may remain stable for many years, exerting a preservation effect on the body.

Drying and Mummification

Postmortem drying of remains is commonly seen in the early stages postmortem. This can frequently be seen in the extremities (e.g., fingers and toes), lips, and genitals.

In dry, low-humidity environments, remains may become mummified. The skin becomes desiccated and takes on a dark leathery appearance. Putrefaction and insect activity may continue within the body, resulting in a skeleton within a shell of mummified skin. In extreme environments or where low temperatures inhibit microbial and insect activity, the entire remains may become desiccated, including internal organs and other soft tissues.

Animal Activity

The progression of decomposition may further be modified by the actions of carnivorous animals. In situations where death has occurred in a confined place in the presence of pet animals, it is not uncommon for dogs and cats to consume remains. The soft tissue from the face and extremities are commonly eaten in these circumstances.

In outside environments, remains may be exposed to wild carnivores and farm animals. In such cases, in addition to consumption, remains may become disarticulated and distributed over a wide area.

Decomposition of Hard Tissue and the Fate of Skeletal Remains

Skeletonized remains are less attractive to necrophagous insects and animal scavengers and their decomposition takes place over a much longer time frame. Bacterial and plant activity continue to have a role in the breakdown of hard tissue, but other chemical and physical actions, such as weathering and abrasion, also influence this process.

Once remains are skeletalized, the substrate onto which or into which they have been deposited assumes greater importance than it did during decomposition itself. This soil pH is of critical importance, for instance, in determining skeletal element survival in burials. Unfortunately, little is known about skeletal element weathering and damage and movement outside of the studies published by archeologists and vertebrate paleontologists. These are focused on the identification of

stages of sun bleaching and drying, scavenging and transport within hyena dens, fluvial transport and stream bed accumulations, and the like – variables that are, generally speaking, somewhat more relevant to prehistoric assemblages and the African environments, which were the impetus for their formulation, than to the majority of modern forensic casework scenarios. Having said that, however, C.K. Brain's early research into the taphonomy of the karstic caves in which the bones of South African fauna and australopithecines accumulated has proved relevant to the interpretation, by Simmons in 2002, of contemporary execution site deposits of the victims of war crimes in Bosnia. The drawback to many of these studies is that the environment in the African Savannah, or Weldt, is quite dissimilar to, for example, temperate forests of North America, rain-soaked pastures in the United Kingdom and the like, and little if any research has been undertaken experimentally to catalog the progression of the processes in other environments from fresh bone through weathering. Several new studies have, however, examined color changes in bone and teeth as correlated to both UV radiation exposure and fluctuating humidity.

Diagenesis, also known as chemical weathering, is the exchange of ionic components between bone and the environment; in most cases, the soil. Once the collagen component of bone has been lost, chemical decomposition predominates and calcium ions leach into the soil in exchange for protons. Metal ions present in the soil (e.g., iron and aluminum) remove phosphate ions from the bone. The rate and degree of diagenesis are dependent on environmental factors, not least the chemical composition of the soil. Physical weathering constitutes the action of wind, sun, and wet/dry cycles. These physical forces create cracking and flaking of bone, thereby accelerating its destruction. Behrensmeyer defined six stages of bone weathering and their relationship to years since death.

Carnivore and rodent scavenging are also factors that affect bone over time. Haglund's research concerning disarticulation patterns commonly encountered in carnivore scavenging suggests that one of the last portions of the body to become separated is the thoracic vertebrae; therefore, it has been suggested that the location of articulated thoracic vertebrae may indicate the site of original body deposition. Likewise, Haglund also studied patterns of rodent scavenging on human remains in forensic contexts. Both rodent and carnivore scavenging can occur in urban as well as rural environments, indoors and outdoors.

Stages of Decomposition

Early stage postmortem changes are often described as being early (<2 h) or late (>2 h). A number of past studies have attempted to extend and refine postmortem stages to include the more advanced decomposition and skeletonization. Using a retrospective case study of human corpses, in 2005 Megyesi et al. introduced total body score (TBS), a standardized system for scoring decomposition in a human corpse. The system assigns a score to each of the three body areas (head and neck, trunk, and limbs), the score relating to observable changes on an advancing scale from fresh to skeletonized. The sum of the three scores is the TBS. This has become the chosen method of assessing decompositional stages by forensic

anthropologists, and together with earlier work conducted by Vass et al. introducing the concept of accumulated degree days (ADD), has enabled more accurate estimation of PMI in cases of advanced decomposition.

Time since Death (PMI) Estimation

One of the fundamental questions arising in any forensic case is how long the remains have been where they are found and how long the individual has been dead. Similar to the most aspects of forensic anthropology, estimating the PMI is not an exact science, but in recent years (owing to the incorporation of two key concepts: ADD and TBS), the assessment of time since death has become, at least theoretically, more straightforward.

ADD was introduced into the anthropological literature in 1992 by Vass et al., although the concept of accumulated degree hours had been part of the entomological literature for some time. Vass et al.'s paper presented an experimental study based on volatile fatty acids in the soil under human cadavers. The critical concept of ADD as a measure of the variables of time and temperature combined allowed the calculation of PMI based on ADD and body mass. The concept operates on the same principle that water will boil at 100 °C no matter if you boil it on high heat for a short period of time or low heat for a longer period of time. Whenever the water accumulates enough temperature (100 °C), it will always boil. With ADD, the concept is that every corpse should display the same characteristics ('boil') once it has accumulated the same temperature. No matter where geographically or in what environment, once a corpse has accumulated a certain temperature (1285 ADD according to Vass et al.) the corpse will be skeletalized. Vass et al.'s data came from examining the volatile fatty acids leaching from the corpse into the soil and the time of skeletalization was when these were no longer detectable; this of course does not equate to the appearance of a dry skeleton, rather that the corpse is no longer undergoing active (wet) decomposition. Thus, above the developmental threshold for most insects (given as 5 °C), a corpse can reach 100 ADD in a myriad of different ways, for example, 5 days at 20 °C, 4 days at 25 °C, 10 days at 10 °C, and so on. All human remains will have a similar appearance at a particular ADD no matter how many days it has taken to accumulate that temperature.

The benefit of using ADD is that it allows researchers across a variety of geographic regions and environments (e.g., with differences in temperature) to compare the rate of decomposition data. When, in the past, researchers reported that it took X many days for a corpse to decompose (or to reach a particular stage), the results were rarely analogous to the same number of days elsewhere. It is unfortunate indeed that the Vass et al. article was largely ignored by taphonomists for over 12 years, quite likely because the article was published under the pathology biology section of the *Journal of Forensic Sciences* and contained complex equations and chemical analyses. It was never cited in either the 1997 or the 2002 volume of Haglund and Sorg at all. Only in 2005, when Megyesi et al. published a paper introducing the concept of TBS did the utility of ADD resurface for assessing PMI and come to the attention of researchers.

The use of TBS was based on Galloway's stages of decomposition published in 1997, but Megyesi et al. refined the descriptions associated with these stages and assigned numerical values to them, much as age-related changes in the pubic symphysis or sternal rib ends were assigned to successive phases. The underlying assumption to all of these methodologies is that one must pass through each successive stage in order to arrive at a subsequent one. Although mummification and adipocere may occur during decomposition, these are not ubiquitous features of the progression and thus may confound one's assessment of time since death. Megyesi conducted a retrospective study of cases where the dates of disappearance (death) and recovery were known; weather station data were used to calculate average daily temperatures and determine the ADD for the interval the person had been missing. She then examined the autopsy photographs and descriptions and scored the body's state of decomposition and assigned a TBS. A regression formula was calculated so that when TBS was known, the formula would predict the ADD. From the ADD, weather station data could be examined in order to subtract each average daily temperature backward from the date the corpse was found until the minimum and maximum dates for disappearance were computed.

As Vass et al. noted in 1992, body mass also affects the rate of decomposition and weight correction factors were provided for assessing ADD to skeletalization. Smaller corpses decompose at faster rates than larger ones, primarily due to the amount of tissue present for insects to consume. Additional studies indicated that the original categories provided (in increments of 50 lbs or 22.7 kg) were not accurate for predicting ADD from TBS and further research is needed to refine this relationship. While Megyesi et al. indicated that they could find no difference between indoor and outdoor rates of decomposition in their study, the sample size of indoor bodies was quite small. Later research by Simmons et al. in 2010 indicated that there is a statistically significant difference between insect-mediated decomposition and decomposition when insects are excluded. There is no difference, however, in the rate of decomposition with regard to the environment in which the insects are excluded from the process; whether deposited in water, a burial, or indoors, a corpse will decompose at the same, slower rate. Furthermore, the rate of decomposition in carcasses where insects are excluded remains the same regardless of body size. A formula for predicting ADD for decomposed human bodies in UK waterways was provided by Heaton et al. in 2010.

Trends in Current Research

The past 5–10 years have seen a great expansion in taphonomic research, although sadly, much of the research being conducted has still been poorly designed, for example, with sample sizes of only two to three individuals per 'experiment,' absence of controls and lack of standardized variable measurement (e.g., the continued use of 'days' rather than ADD) and hence have produced little usable data. As in reports of case studies, these remain largely anecdotal in nature and thus would be inadmissible as the basis for evidence in a court of law. There is a great need for both the accumulation of more (standardized) data at the existing decomposition facilities and

for the continued testing of a variety of variables that may affect the decomposition process, whether in rate or in pattern, but these must be conducted as replicable scientific experiments with sufficient numbers of experimental and control subjects, standardized variables, measureable data, and robust statistics.

There is a continuing debate concerning the value of animal-based research and whether it is applicable to human decomposition. There are certainly pros and cons to both animal- and human-based decomposition research. Decomposition research on human cadavers benefits from direct comparisons and applicability to forensic case work. However, it is limited by the availability of donated cadavers and refrigerated storage capacity that might facilitate conducting controlled experiments. Unfortunately, none of the human decomposition facilities has actually conducted and/or published any experiments involving sufficient numbers of experimental and control individuals, and in truth, very little published hard (more than purely descriptive) data have been forthcoming from these facilities. Although data for forensic casework should ideally be based on human analogs, what has been published on human decomposition cannot, thus far, provide a statistical basis for deriving a probability of occurrence, and hence, would not be acceptable in court given the new rules of evidence and expert testimony.

Decomposition research using animal models (namely, *Sus scrofa*, the domestic pig) obviously suffers from using subjects that are not directly analogous to human forensic cases and, though skin, an omnivorous diet and gut construction are indeed similar to those of humans, the limb proportions, bone lengths, head shape, and so on, are not, thus making it hard to draw relevant conclusions with direct correspondence to the human form. On the other hand, animal models allow for the employment of a far greater sample size incorporating sufficient controls and experimental subjects from which to reach statistically sound conclusions. Using animals allows for the repetition, replication, and validation of results. One can also conduct studies on the animal subjects, which one might not receive permission to conduct on donated human cadavers (e.g., inflict and study a variety of traumatic insults – gunshots, burning, etc. – upon them). Both types of research are subject to similar, stringent ethical review, and in the case of animals, one must be compliant with the guiding principles of reduction, refinement, and replacement.

Trends in future research need to take taphonomic studies beyond observations and descriptions and the subjective. Taphonomic researchers should fully explore the decomposition 'myths' regarding what does or does not influence decomposition rate and pattern, and researchers must do so using both standardized methods of scoring decomposition and ADD to allow the comparison of results over disparate chronology, geography, and environment. Further systematic experimental research regarding weathering and bone diagenesis is also warranted in order to extend and refine PMI estimates beyond decomposition and into taphonomic intervals where skeletal elements alone persist. Equipment such as weather stations, thermocouples and data loggers (internal), thermal imaging cameras, time-lapse photography, endoscopes to visualize decomposition internally, and so on, should also aid in elevating taphonomic research from the merely descriptive to higher scientific standard, reliability, and admissibility in court.

Archeology

Background

Forensic archeology first emerged in the United States in the later 1970s as part of a broader recognition of the role of anthropology in medico-legal matters. There the development of forensic anthropology has been well charted, with professional competency being recognized by the American Academy of Forensic Sciences. However, in Britain, where archeology was traditionally seen as a free-standing discipline with roots embedded more strongly in excavation and field skills, forensic archeology developed somewhat later. Furthermore, differences in medico-legal practice at scenes of crime between the two countries also serve to confine the role of forensic archeology in Britain to one more specifically concerned with field activities than with postmortem study. Elsewhere, forensic archeology plays a less prominent role in criminal investigation, although with formal interest now developing in other parts of northern Europe, in particular, the Netherlands and Australasia. In addition, the excavation of mass civil or war graves relating to both recent and socio-historic conflicts in places such as Argentina, Rwanda, Bosnia, South Africa, Spain, and Eastern Europe has widened the application of archeological recovery techniques to other parts of the world.

Archeological input to criminal investigation reflects the skill base of modern archeology and its role in society. In Europe and the United States, archeologists are now extensively employed on behalf of central and regional government in order to identify and assess archeological remains ahead of planning and redevelopment schemes. The archeologist's interest is almost exclusively concerned with understanding the past from buried material remains; this can be expressed in general terms of finding evidence, recovering evidence in a manner that will maximize its value, and interrogating evidence in order to reconstruct sequences of past events. As a process, this has much in common with law enforcement detection and is now widely recognized as having a role in modern forensic investigation when buried remains are encountered. This skill base provides a collective expertise in landscape analysis, knowledge of resources (photographic and cartographic), geology, land use, site location methods, and excavation techniques.

In addition, archeology is a process that has access to a range of associated areas of specialisms, many of which also have forensic application. These include, for example, aerial photographic interpretation, identification of pollen assemblages, soil analysis, animal/human bone differentiation, and recognition of cremated human materials. Archeologists have also developed some techniques that are peculiarly suited for forensic purpose, for example, geophysical survey for the detection of shallow subsurface remains. Archeology, such as forensic science, is also concerned with scientific analysis across a broad range of material types.

The main areas of interest common to both archeology and criminal investigation might be listed as follows:

- skeletal analysis (physical anthropology),
- scientific analysis,
- field search, and
- excavation and recovery.

The first two of these are completely discussed elsewhere in this volume and are not detailed here other than for cross-reference purposes. Skeletal analysis, for example, is a major section in its own right with a recognized modern history in criminal matters as well as in military and disaster scenarios in the United States, Europe, and Asia. Equally, the application of both physical and life sciences is now a fundamental part of modern archeology and much analytical science is dedicated to matters of provenance or dating. Provenance – the ascribing of a finished product (e.g., pottery) to the location of a source, or place or company of manufacture – is a well-attested method of evaluating the trade, transport, and social economics of earlier societies. Like forensic science and the Locard principle, it ascribes a material to a parent source. The methods used are also common to forensic science, as indeed are many of the materials under study (e.g., silicates, soils, metals, and pigments). There are many cross-reference points throughout this volume, although interplay between the two disciplines of forensic science and archeological science, respectively, is curiously exclusive.

Absolute dating methods also have some relevance here. Although archeological and forensic time scales have little in common, radiocarbon dating has some application in demonstrating whether human remains pre- or post-date 1952 (the era of atomic weapon testing, which generated high atmospheric radiation levels). This is particularly important in providing coarse dating in instances of stray or displaced human bone, and also for determining if remains are of 'forensic significance,' particularly in countries where a 70-year rule for the pursuit of prosecutions applies. More relevant, perhaps, is the observation of taphonomic (decay) processes in buried environments and the determination of interval since deposition. There has been considerable interest in recent years in the degradation of both human and associated modern materials buried over short timescales.

The number of homicide victims who are ultimately buried to avoid detection is relatively small in relation to the total of homicide victims, although several of these have been multiple or serial killings and have been of high profile. A greater percentage involves concealment in one form or another. Recent history has emphasized a number of cases that have demonstrated a potential role for archeology: in the United States, these have been highlighted by one of the pioneers of forensic archeology, Dan Morse, from cases in Illinois and Texas; in Britain notably from the Moors Murder enquiry in

the early 1960s; and the later investigation of the north London garden of Dennis Nilsen in 1984. All these situations were effectively archeological scenarios, which would have been approached and handled in very different ways if taken on a straight archeological basis. However, since the late 1980s, but with some notable setbacks, such cases have been fewer and awareness of the potential value of using archeological techniques has increased among law enforcement agencies. Indeed, many so-called 'cold cases,' where the time since deposition may range from 2 to 70 years, are being revisited utilizing archeological techniques in light of this. It is, nonetheless, not simply a straightforward matter of creating awareness or applying appropriate techniques. The process is two-way: archeologists also need to recognize the protocols and processes of crime scene work; the time scales involved; and, most importantly, the judicial constraints that surround forensic work. The philosophy and practice of forensic archeology is very different from that of its parent. Also, different are the objectives and the means to achieving those objectives (see section [Recovery](#)).

Archeology is based on the principles of stratigraphy, namely, that the ground subsurface comprises discrete layers of earth, which differ in texture, color, and physical properties reflecting the effects of both natural and man-made activity over time. These layers can be generated by natural processes of soil formation or, in areas of habitation, by building, farming, and general development caused by a wide range of activities. In rural areas, these layers can be of relatively shallow depth above bedrock (i.e., a few centimeters) or in urban areas up to several meters deep reflecting centuries of activity and use. Archeologists try and interpret what each layer represented in past time and also how the various layers relate to each other chronologically. The order of their formation can usually be determined quite easily. Many modern layers, particularly those relating to building activity, may be able to be dated by modern records.

In effect, the profile of layers in a given area of the subsurface makes a type of statement about the history of that place. It also presents a 'snapshot' in time, in that all the layers have a broad chronological relationship in which one layer that overlies another is clearly of later date ([Figure 1](#)). If a grave is dug into the ground, the existing layers in that place become disturbed; a relationship occurs between these layers and the grave; and the timeframe of the overall stratigraphy becomes extended. Archeology involves identifying and interpreting changes of this type.

A grave identified within these layers will have a contextual integrity, no matter how few layers are involved. Recovering or excavating a victim without awareness of related layers (i.e., the layers that are earlier than the grave, the layers that are later than the grave, and the grave itself) will stand to lose much of the evidence that may be available. Questions that the pathologist or medical examiner will try to answer pertaining to interval since death, identity, or the cause/manner of death may be more readily resolved if the edge and sides of the grave can be defined in three dimensions; this effectively identifies the physical boundaries within which the human remains and associated materials will be found. The presence of the associated layers may assist in dating the event.

Human remains often appear during building or development work when bones become unearthed during machine

Figure 1 Example of local stratigraphy showing development of layers through time, including wall (right) and later pit or grave (top left). Drawing by H. Buglass.

excavation. In such instances, it is particularly important that remains are retained in situ in order that the relationship of the grave within its buried environment can be retained as much as possible.

Search

Locating buried materials can involve a range of target types, although the most common are human remains. Other targets can include firearms, drugs, or stolen goods covering all shapes, sizes, and materials of organic, inorganic, ferrous, or nonferrous type. In nearly all instances, the method of search involves the identification of the disturbance caused by the burial in the first instance, rather than the item buried. Even with homicide victims (for which this entry is primarily intended), the target characteristics can vary according to stature, age, clothing, or dismemberment.

The initial phase of search usually involves targeting the most likely locations in a given area using factors of feasibility (i.e., geological suitability, soil cover, land use, etc.) in combination with a suspect's movement, psychological profiling, and other intelligence. 'Dump-site' analysis, as it is known, has been the subject of valuable research in both Britain and the United States: it enables factors such as the relationship between victim and suspect, location of last sighting, or likely distance traveled to be fed into the search equation. The use of geological maps and existing aerial photographs (vertical and oblique) can facilitate this. Often, the process can be carried out as a 'desktop' study, sometimes using geographical information systems, and the target areas are located accordingly. This is highly desirable, as it neither arouses suspicion, runs the risk of damaging evidence on the ground, nor necessarily incurs great expense. It also allows what are known as site histories to be devised, which details any landscape change

(natural or man-made) that may have affected the burial environment or caused disturbance to the remains.

Once the area can be narrowed down, a more detailed approach can be taken. When a victim, or for that matter any object, is buried, the subsurface is disturbed in relation to the surrounding environment. This disturbance can have a number of effects on (1) the subsequent ground vegetation, (2) the immediate topography, and (3) the geophysical signature of the disturbed area.

The original digging of a grave is likely to create a looser, damper, more aerobic area of ground when the grave is filled in. This will almost certainly affect the height or density (or even species) of the resulting vegetation on the ground surface (Figure 2) – an effect that may become more pronounced as the human decay process provides nutrients to an already moistened soil medium. The converse might apply if the grave was filled in with stones and the vegetational growth inhibited accordingly. These changes will have a long-term effect. There will also be a shorter term effect on the surrounding ground surface, where the excavated soil was dumped when the grave was first dug. There may also be excess soil providing a low mound over the grave, which in time may sink to form a depression as the grave infill consolidates. A secondary depression may occur as the body cavity collapses, and cracking may take place at the grave edges during dry weather. In addition, the infilling of the grave may contain obvious traces of deep disturbance, such as soil or bedrock of different color (e.g., clay or chalk) brought to the surface in an otherwise undisturbed area.

Although many of these features of vegetation, topographic, or soil change might be seen at ground level, they are often at their optimum when viewed from the air, some features being particularly prominent through the use of shadows at appropriate times of the day. Aerial reconnaissance is an ideal nonintrusive primary method of search, but its effectiveness may be seasonally specific given that light and land use are variable components. The value of historic aerial imagery in criminal investigations involving buried remains has also recently been realized. Any photography, however, may be supported by imagery analysis for which there is now highly developed military and archeological expertise is available.

There are a number of methods that can be used to detect buried remains; some of the most commonly used are listed below on a scale that runs from the noninvasive (i.e., those least likely to destroy buried evidence) to the invasive

(i.e., those most likely to destroy buried evidence). The list is not comprehensive and is presented only as a general guide; it also tends to reflect the selective narrowing down of the target area. The deployment of these techniques, and their complementary or sequential use, depends on a range of factors including the local environment, the geology, the nature of the target, and the interval since burial. Some techniques, particularly geophysical methods, are only suited to certain types of environment or situation (e.g., indoors, outdoors, concrete, soil, and clay) and are wholly ineffective in other environments. It is not possible to outline the complex range of variables in the space available here; search is a specialist area of expertise for which advice should be sought (see below). The primary use of one method may completely negate the effectiveness of another or may be wholly wasteful of resources. A routine list of techniques might be as follows:

- Aerial photography and reconnaissance for the detection of disturbances identified from the vegetation or topography (shadow or color change) or by soil marks (color).
- Field craft for the detection of discrete areas of vegetation, topography, or soil difference; for the presence of ground cracking; and for the identification of burial locations by using prominent local landmarks or features, which may have been used as guide points by the offender (sometimes known as 'winthroping').
- Body-scent dogs for the identification of buried remains by virtue of characteristic odor, which may be released from the ground by systematic or selective probing.
- Geophysical survey for the detection of shallow subsurface features, typically by using electrical resistance (to detect disturbance that has affected local moisture content of soils), magnetometry (to detect disturbance caused by changes to a local magnetic field), ground penetrating radar (to detect responses to changes in ground density using an electromagnetic pulse), and metal detector (to detect both ferrous and nonferrous items associated with buried individual).
- Probing/sampling for the identification of subsurface disturbance, emission of methane, or thermal change.
- Excavation for the identification of soil disturbance (color, texture, and physical properties) and changes consistent with a grave (see section [Background](#)).

The principle on which all of these methods are based is the ability to detect a disturbance or change within an otherwise

Figure 2 Some potential effects of burial on surface vegetation. Drawing by H. Buglass.

undisturbed environment. Also to be considered are effects brought about by the decay process of the body itself. This may not only generate heat (and allow the target to be identified using thermal imaging during the decay activity) but also affect the geophysical properties of the grave and inhibit or enhance the likelihood of detection depending on the survey technique used. Variables that might accelerate or delay this decay process include factors of depth, climate, soil pH, wrapping or clothing, water content, and presence of oxygen. Optimum methods of search rely on knowledge of as many of these variables as possible.

In light of the closure of the Council for the Registration of Forensic Practitioners in 2009, under which practitioners could become registered as competent, the Forensic Archeology Special Interest Group and Expert Panel was created in 2011 in the United Kingdom under auspice of the Institute for Archeologists. The Special Interest Group aims to raise awareness of the discipline and developing a training network for students. The Expert Panel consists of a group of specialists who have undergone proficiency testing and were deemed competent based on their experience in criminal investigations as 'reporting' practitioners (i.e., those who have given evidence in court). Members adhere to a Code of Practice and are responsible for designing operational standards. Most are employed by universities and fewer by private firms or as independent consultants, but they are all actively engaged in both casework and research concerning search and recovery.

Recovery

Although recovering buried remains can occur in a variety of different situations and environments, the process of recovery follows a well-established routine in order to maximize the evidence available. This is based on the awareness that archeology is a destructive process and that each recovery operation is seen as a nonrepeatable exercise.

When the burial of a victim takes place, three main activities are undertaken: the physical removal of earth from the ground, the deposition of the body on the grave, and the infilling of the grave. Proper forensic investigation of the grave follows this process in the reverse order: the body is exposed in order to show the manner in which it was disposed, the body is lifted, and subsequently the manner in which the grave was dug is identified.

Once the outline of a disturbance has been identified, it is normally half-sectioned (i.e., half of the infill should be excavated), usually by bisecting the long axis at around the midway point leaving an exposed vertical profile of the unexcavated part of the disturbance. This has two main benefits: first, it serves to identify whether the disturbance is in fact a grave or not without excavating (and destroying) the whole disturbance, and second, it provides visible evidence in the exposed profile as to how the disturbance was infilled and how it might most effectively be excavated to resolve questions pertinent to the particular case.

Sometimes, because of depth or other constraints, it becomes necessary to extend the working area available by excavating additional space adjacent to the grave itself (having first suitably recorded the grave sides). This allows lateral access to

the grave/body and facilitates proper excavation. In situations where this is impossible, it may be necessary to construct struts or planking to wedge across the grave as a working platform. This ensures that the weight of the excavator is taken by the planking rather than the underlying victim (at whatever depth), thus minimizing unnecessary damage to the victim and to any associated materials. Although no two scenes are ever the same, and each has a different situation and timescale, a number of general elements need to be addressed during the recovery process. These are outlined below and should only be seen in general terms, given the great variability of situations and constraints of individual scenes.

- *Preserving the integrity of the grave.* It is critical that the integrity of the grave (i.e., the boundaries and area of disturbance) is maintained throughout, in order to preserve the exact situation that occurred when the victim was buried. This not only allows the original scene of crime to be recreated but also ensures the absolute recovery of the individual and any associated materials. Furthermore, determination of the parameters of the grave is also necessary in order to eliminate the possibility of contamination.
- *Emptying the grave.* The grave infill is normally removed by trowel in layers, which reflect the manner in which the grave was infilled by the perpetrator. This also enables the nature of the grave infill to be identified. If there are no observable layers, the grave infill is excavated in a series of 'spits' typically 10 cm deep in order to provide a controlled removal of the grave deposits.
- *Objects found within the grave.* Exhibits discovered within the grave are normally recorded in three dimensions within the layers or 'spits' in which they occur. Recording of this type is now a standard practice on archeological sites and is carried out using an electronic distance measurer, which is both accurate and rapid. This ensures that individual objects are properly associated with any layers in which they occurred and that the contents of the grave can be recreated spatially. These exhibits can include items belonging to the individuals, such as clothes, buttons, jewelry, the contents of pockets; items associated with the burial event, such as a weapon, papers, clothing, and wrapping; or materials introduced to the grave infill in an attempt to minimize discovery, such as rubble or lengths of wood.
- *Recording.* Because archeology is a destructive exercise, the recording process is comprehensive and wherever possible is undertaken in three dimensions. The outline of the grave is normally planned with reference to permanent base points at ground level in order that it can be relocated in the future; the base and the profile of the grave are planned using graphic conventions such as contours or hachures and a vertical record of the infill from the half section (above; also [Figure 3](#)). This section is drawn as a part of the basic recording methodology and is essential in demonstrating the dimensional properties of the grave. In addition, the development of laser scanning technologies offers the potential in the future for the digital recording of grave sites.

On archeological sites, human skeletal remains are drawn to scale as a part of the recording process; this may not be possible at a scene of crime, but the disposition of the body and the location of any associated features are usually subject

Figure 3 (Left) Vertical profile of grave infill taken at approximately half-way point across disturbance. (Right) Hachure plan of overall grave profile on completion of excavation and removal of victim. Cross-reference provided by section line A-B. Drawing by H. Buglass.

to detailed photographic record. The body is normally revealed entirely before lifting. The lifting process itself is a delicate operation, which takes place bearing in mind that footprints may have survived in the floor of the grave. The method of lifting varies depending on factors such as depth, condition, and wrapping but is often most satisfactorily carried out by sliding a board or metal sheet under the body, although this may have implications for the survival of any foot impression.

Photography occurs throughout the recovery process, ideally taken from a fixed point at one end of the grave (normally the foot end) and identifies specific rather than arbitrary points during the recovery process, for example, before excavation, at changes in layers or 'spits' in the grave infill, at the point where significant exhibits occur, when the body is exposed and when the body has been lifted. These photographs will not only record the main sequences of events but, viewed in reverse order, also recreate the offense in exactly the way it occurred.

Excavation and record along these lines may be able to answer several important questions about the original crime:

- How was the grave dug and with what implement? This may be resolved by examination of the sides of the grave, which exhibits mechanical grab, shovel (curved edge), spade (straight edge), or pick (short blade) markings. In exceptional instances, it may be possible to identify a specific implement that bears characteristic markings or nicks on the blade. This is especially the case in soils that sustain impressions such as heavy clays.
- Was the grave dug in a hurry or was it carried out carefully in a prepared way? The professional opinion of the archeologist may be canvassed in an attempt to determine whether a grave site was premeditated on the basis of its profile and depth (or even of its primary silted deposits if the grave had been open for some time before burial). This clearly has implications for manslaughter or murder charges.
- Did the grave contain any evidence of cause or manner of death? The infill of the grave may bear traces of toxins, blood, or firearms discharge and the excavator will be prepared for these within the grave deposits. Toxins will normally be the subject of a sampling strategy by the scene of crime personnel. The location of bullets/pellets may be

determined by the use of a metal detector. Bullets may, for example, have passed through the base of the grave into the subsoils if the victim was shot in the grave itself.

- Was there transfer of materials from offender to grave infill? Locard's principle points to the natural transfer of materials (e.g., fibers, hair, sweat, or footwear impressions) into the grave infill. These are often extremely hard to identify or recover but should be borne in mind during the recovery operation.
- Was there foreign material in the infill or layer matrices, and if so where did it come from? During the excavation, the descriptions of individual layers or 'spits' are recorded using accepted soil definitions and terminology. Soils or materials that are unlikely to have been dug out from the area of the grave can provide additional evidence. Their provenance may have considerable bearing on convicting the offender.

Summary

Forensic archeology is now an acknowledged area of expertise in field search and recovery and has been legally recognized in prosecution and defense areas during the late 1980s and 1990s in both the United States and Britain, as well as being actively developed in other European countries. It has been recognized as a subdiscipline in its own right and is offered within university degree programs on both sides of the Atlantic. Forensic archeology also features in postexperience and validated postgraduate courses and seminars intended for both archeologists and law enforcement personnel, forensic scientists, and associated professionals. Despite its academic origins, its familiarity with sampling, three-dimensional study, and recording processes lends itself naturally to scene of crime investigation. Furthermore, its extensive repertoire of associated disciplines provides a valuable range of distinctive forensic skills.

Postmortem Interval

DH Ubelaker, Smithsonian Institution, NMNH, Washington, DC, USA

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Arthropods Invertebrate organisms of the phylum Arthropoda (includes insects, crustaceans, arachnids, and myriapods).

Barnacle Marine crustaceans.

Entomology The scientific study of insects.

Sphagnum A type of moss.

Estimation of the postmortem interval of relatively recently deceased individuals in early stages of postmortem change generally falls within the discipline of forensic pathology. Such estimations depend on observations of the condition of the soft tissues of the cadaver but often are supplemented with information from the context of the recovery site, as well as what is known regarding the deceased individual's activities during life. Accuracy is strongly correlated with time since death. As the postmortem period increases, the time range and difficulty of estimation increase as well.

In the immediate postmortem period, body temperature (algor mortis), the extent of body muscular relaxation, body stiffening (rigor mortis), skin discoloration (livor mortis), and the stages of decomposition all provide valuable clues. The early stages of decomposition include both autolysis (break down of tissues by digestive enzymes) and putrefaction (impact of bacterial activity). However, research and casework experience have revealed that many factors can influence these processes and complicate interpretation. Such factors include climatic conditions, clothing, body temperature at time of death, postmortem environmental context, and ante-mortem conditions of the individual (body size, muscular development, pathological conditions, and age at death).

With advanced decomposition and/or alteration of human remains by thermal events or fragmentation, the need for anthropological perspective becomes enhanced. This perspective relies extensively on observations of the conditions of both soft and hard tissues but is supplemented by expertise in entomology, botany, and other fields.

Entomology

Forensic entomology plays an especially important role in assessing the early stages of decomposition. Although this represents a field distinct from forensic anthropology, anthropologists frequently are involved in the recovery of entomological evidence and/or recognize the need for evaluation by entomologists. Although many different kinds of arthropods can be involved in human decomposition, the two most important groups are flies (Diptera) and beetles (Coleoptera). The flies are attracted to moist tissue and thus are early arrivals to remains. The fly larvae are responsible for considerable reduction of soft tissue. In the chain of arthropod succession, beetles generally arrive later, being attracted by more

desiccated tissue. Other arthropods may also arrive to consume feeding insects. A forensic entomologist may collect adults, eggs, and larvae; identify the type of arthropod present; and use that information to assess time since death.

Blow flies (a large family of flies including the secondary screwworm fly (*Cochliomyia macellaria*), the Arctic blow fly (*Protophormia terraenovae*), green bottle fly (*Lucilia* sp.), blue bottle fly (*Calliphora vomitoria*), and bronze bottle fly (*Lucilia cuprina*)) are of particular entomological interest. Adult flies deposit large numbers of eggs that rapidly hatch. The larvae (maggots) molt into multiple instars before the formation of the puparia and the emergence of the adult. The timing of each of these growth stages has been researched, enabling this information to be used to estimate time since death. Interpretation also considers temperature and other relative information.

Botany

A variety of botanical evidence also can provide useful information if properly recovered and documented. Roots from plants growing nearby can penetrate human remains and their immediate surroundings. If properly sampled, identified, and assessed, roots can reveal a minimum time since death. In such studies, the association with the remains must be clearly established. Leaves, branches, and a variety of other plant materials also can prove useful depending upon the circumstances of the case.

Other Animal and Cultural Indicators

Anthropological assessment of postmortem interval can also be aided through many other biological materials that might be associated with human remains. Examples can include barnacle formation in marine environments and the presence of the nests of flying insects. Evaluation by the appropriate specialist may reveal the minimum time required for the evidence to have been associated with the remains.

Observations of cultural practices also may provide vital clues. Patterns of dental alteration, skull deformation, or even trephination (surgical-type alterations in crania) may suggest an ancient origin of human remains. Extreme dental wear (attrition) suggesting a very rapid rate of wear was common in ancient times but rare among modern populations. Certain types of surgical practices and orthopedic devices also can be dated, linking remains to particular periods of the past.

Tissue Morphology

Traditionally, forensic anthropologists have evaluated time since death utilizing observations on the extent of preservation of soft and hard tissues. However, casework and experimental research have revealed the complex taphonomic factors that affect soft-tissue decomposition and hard-tissue alteration, complicating this assessment. Primary influencing factors include temperature, environmental pH, amount of moisture, and oxygen availability. Other related factors include age and constitution of the individual, body treatment after death, extent and type of injury to the individual, extent of exposure to scavenging animals, protection by clothing or other materials, climate, seasonality, burial type, burial depth, and local vegetation patterns.

The timing and pattern of postmortem change demonstrate regional variation and even differences in microenvironments within regions. Dry environments can induce rapid bloating followed by extensive mummification. In contrast, a body exposed above ground in a tropical environment can be reduced to a skeleton within 2 weeks. The decomposition process can be influenced by mechanical injury as well as extensive freezing and thawing.

Although the exceptions are impressive and extensively influenced by the factors discussed above, a general sequence of postmortem alteration has been noted in temperate climates. This sequence begins with fresh remains with no discoloration and then proceeds through early decomposition and advanced decomposition and culminates in skeletonization. In their research, Megyesi et al. noted that the manifestation of these stages varies in different areas of the body. Their research indicates that, for the head and neck, early decomposition begins with a pink-white appearance with some skin slippage and hair loss. The process then proceeds to include gray to green discoloration with some retained fresh-appearing flesh. This is followed by desiccation of the nose, ears, and lips with brownish discoloration at the margins. Later, fluid is purged from the eyes, ears, nose, and mouth with some bloating of the neck and face. This stage culminates in brown to black flesh discoloration.

Advanced decomposition in the head and neck begins with a caving in of the tissues of the eyes and throat. This stage is followed by some moisture retention but less than 50% bone exposure. The remaining soft tissue then becomes desiccated.

The skeletonized stage begins with bone exposure progressing to more than 50% of the area with the presence of greasy material and some decomposing tissue. Desiccated tissue is then recognized followed by dryness of the bones themselves but with some grease retention. The final stage is represented by dry bones.

For the trunk, Megyesi et al. recognize a slightly different sequence. The early decomposition process begins with a pink-white appearance with some marbling and skin slippage. This proceeds to a gray/green discoloration with some retained fresh-appearing flesh. Bloating then occurs with green discoloration and fluid loss. A post-bloating phase then involves gas release and black discoloration.

Advanced decomposition of the trunk begins with caving in of the abdominal cavity and general sagging of flesh areas

followed by moist-tissue retention but less than 50% bone exposure. The remaining tissue then becomes desiccated.

The final skeletonization stage of the trunk is marked by retention of some body fluids and grease. Retained desiccated tissue then covers less than 50% of the area. This is followed by largely dry bones but with some grease retention. The final stage is dry bones.

For the limbs, Megyesi et al. note that early decomposition begins with a pink-white appearance with some skin slippage of the hands and/or feet. A gray/green discoloration then occurs with some marbling and fresh flesh retention. Desiccation of the fingers, toes, and other areas is then noted with some brown discoloration. The skin then takes on a leathery appearance with brown/black discoloration.

Advanced decomposition in the limbs begins with the presence of some moist tissue and less than 50% bone exposure. The tissue then becomes desiccated.

The skeletonization phase begins with more than 50% bone exposure with retention of some body fluids. The bones then become largely dry but with some grease retention. The final stage is dry bone.

Megyesi et al. produced not only the above detailed description of the general sequence of skeletonization of human remains, but also a method to estimate the postmortem interval. Their approach considers not only the stage of decomposition/skeletonization of the remains but also a calculation of degree days in recognition of the key role of temperature in the rate of decomposition.

In 2011, Vass proposed a more complex approach to estimate the postmortem interval. Based largely on research conducted at the University of Tennessee, Vass differentiates processes involved in remains recovered from surface context versus those from the subsurface. The Vass approach also considers temperature, but in addition, moisture and oxygen partial pressure.

Mummification

Mummification represents a variant of the postmortem process usually involving extreme desiccation. Although mummification can occur within dry microenvironments in most locations, it is most commonly associated with arid regions of the world. Since mummified/desiccated tissue is extremely resistant to further alteration as long as low humidity is maintained, its presence can complicate estimates of postmortem interval. In dry regions of the world, naturally mummified remains have been dated to hundreds of years ago. Mummification can also result from thermal factors, chemical factors, anaerobiosis (anaerobic conditions), excarnation (defleshing), and other conditions.

Preservation by cooling represents the primary thermal factor resulting in mummification. While cool temperatures can slow the decomposition process, freezing of course prolongs preservation as long as low temperatures are maintained. Maintenance of low temperature, either accidentally, naturally, or purposefully, can complicate interpretations of postmortem interval. High temperatures also can promote rapid desiccation and mummification.

Chemical factors can include the presence of heavy metals and chelation. Mercury, copper, and arsenic have all been implicated in unusual soft-tissue preservation. Prolonged soft-tissue preservation in the vicinity of copper artifacts represents a well-known phenomenon in remains from both archaeological and forensic contexts. Arsenic also represents a well-known preservative of soft tissue and historically has been used by embalmers. Chelation refers to chemical agents that combine with other materials, reducing their availability to the bacteria of decomposition. Peat bogs are well-known sources of chelating agents that facilitate long-term preservation of soft tissues. The sphagnum in peat bogs also can generate a tanning process.

Other factors that can contribute to the mummification process and long-term preservation include certain resins and spice, lime, lye, salt, and even bat guano. In ancient times, encasement of remains in plaster-like material succeeded in producing long-term preservation of soft tissue.

Adipocere

Adipocere represents a special form of mummification variously referred to as corpse wax or grave wax. Although definitions vary considerably, most recognize its tenacious nature, that it can present a waxy, greasy, or crumbly appearance and can vary in consistency from soft to hard and in coloration from gray to white. It represents a form of arrested decomposition of soft tissue involving saponification of fat/adipose tissue that can preserve aspects of original morphology. The term is derived from the Latin words 'adepts' (fat) and 'cere' (wax), and its use can be traced back to as early as 1789 in France. Chemical analysis has detected the saturated fatty acids of palmitic, myristic, stearic, and 10-hydroxy stearic acid. Unsaturated fatty acids present include oleic, palmitoleic, and linoleic.

Although formation is usually associated with prolonged exposure of human remains to damp environments, adipocere can form in dry environments, water submersion, and cold sea water. Although adipocere most commonly forms in individuals with high body fat and in body areas with an elevated fat component, formation can occur in individuals of all ages, both sexes, and in both embalmed and unembalmed remains. Moisture presence is an important factor, but it can originate from the environment of the remains or from the body itself. Burial in soils that retain moisture can promote adipocere formation but a variety of soils may be involved. The presence of clothing that can retain moisture favors formation. Adipocere formation can be slowed or prevented if the body is protected by plastic. Although climatic conditions of the general environment are important, factors in the microenvironment of the remains are most critical. Factors favorable to adipocere formation include mildly alkaline pH, warm temperature, anaerobic conditions, and moisture. Cold temperature, lime, and aerobic conditions are limiting factors. Clearly, many factors other than postmortem interval are involved in adipocere formation.

Although early indications of adipocere formation have been detected only a few hours after death, clearly visible

expressions usually require weeks. Formation of morphologically apparent adipocere has been reported between 5 weeks and 3 months.

Once formed, adipocere can remain extremely resistant to alteration as long as appropriate environmental conditions are maintained. Adipocere can be retained in remains dating back hundreds of years. However, if environmental conditions are altered, adipocere may degrade. Conditions favorable to the degradation of formed adipocere include air exposure, increased environmental moisture, fungal growth, and the presence of Gram-positive bacteria. Clearly, adipocere formation complicates estimation of the postmortem interval.

Chemical Approaches

A variety of chemical approaches have been attempted to estimate the postmortem interval. Those involving analysis of bone include carbonate analysis, fluorescence, specific gravity, superconductivity, nitrogen content, quantification of amino acids, analysis of neurotransmitters and decomposition byproducts, benzidine testing of bone surfaces, luminal testing, odor analysis, and X-ray diffraction studies of bone crystalline structure. Although these approaches have shown some promise, lack of definition of influencing taphonomic factors has limited their application.

In 1992, Vass et al. reported research on volatile fatty acids resulting from soft-tissue decomposition that could be detected from soil associated with human remains. Experimental research revealed that patterns of volatile fatty acids could be detected in associated soils during soft-tissue decomposition and of specific anions and cations in the skeletal phase. In consideration of degree days, this information offered useful perspective on time since death.

Some research attention also has focused on immunological approaches to evaluating time since death, the fat content of bone, and histological techniques. Immunological approaches document the effect of time since death on properties of bone protein but existing approaches are limited by soil contamination and other factors. Research has documented the decrease in bone fat content over time, especially within histological structures, but measures lack the precision necessary to reliably determine postmortem interval.

Radiocarbon Analysis

In the traditional application, radiocarbon dating provides a widely used approach to estimating the antiquity of relatively ancient remains. Used primarily for remains found in archaeological contexts, radiocarbon analysis can provide absolute dating for remains likely of considerable antiquity. This approach recognizes that the isotope carbon-14 is mildly radioactive and decays at a predictable rate. The half-life of carbon-14 is about 5730 years. The extent of degradation is measured from the standard present in 1950. After about 50 000–60 000 years, most decay has taken place and the amount of carbon-14 is too small to accurately measure. Thus, while radiocarbon dating (using isotopic degradation) has proven useful for analysis of

relatively ancient remains, it generally is not applicable to modern forensic cases, other than to document when cases thought perhaps to be of modern origin are actually of great antiquity.

In recent years, radiocarbon isotope analysis (distinct from radiocarbon dating as described above) has emerged as a very useful approach to evaluating the postmortem interval in modern remains. Atmospheric testing of thermonuclear devices during the 1950s and early 1960s unleashed large amounts of radiocarbon (carbon-14) into the atmosphere. The quantity increased sharply until 1963, when, following cessation of testing, atmospheric levels began a gradual descent. However, in 2011, the atmospheric levels remain above those documented prior to the bomb-pulse period. Through the food chain, these modern elevated levels of radiocarbon have been incorporated into the tissues of all living organisms, including humans. For this reason, elevated levels of radiocarbon represent an isotopic marker of the modern period and can distinguish tissues formed during this period from those that formed earlier. Using this knowledge in regard to recovered human remains, samples can be collected and analyzed for radiocarbon content. If elevated levels are detected, the analysis clearly indicates that the individual was alive during the bomb-curve period. Since the bomb-curve period corresponds generally to the period of forensic interest in human remains, the technique has emerged as a key contributor to postmortem interval evaluation.

Analysis basically reveals average values within the samples submitted and must consider the nature of the tissue analyzed. Dental enamel forms during the preadult years and does not remodel. Thus, even in mature adults, the radiocarbon content of dental enamel reflects dietary radiocarbon levels at the age when the dental crown formed. Bone does remodel but at different rates depending on the type of bone tissue. Cancellous bone, especially that associated with blood-forming tissue (e.g., bodies of vertebrae), remodels more rapidly than compact bone (such as that found in the outer layer of long bone diaphyses). Most soft tissues of the body, especially internal organs, remodel at much faster rates. Thus, analysis of the different tissues presents varying radiocarbon values that document different life stages of an individual. Interpretation of these values with recognition of their formation times allows proper placement on the bomb curve (older ascending portion,

apex, or more recent descending portion). This information, considered with the estimated age at death of the individual, may reveal important aspects of the postmortem interval, the approximate date of death, and even the approximate birth date.

Glossary

Alveolus Socket (or pit) in which the root(s) of a tooth is located.

Antemortem Preceding death.

Calcination Process of high-temperature heating.

Commingled Mixture of bones from more than one individual and/or species.

Cortical bone Dense highly calcified bone primarily found in the shafts of the limb bones (also known as compact bone).

Dentine Yellowish body of the tooth underlying the crown and surrounding the pulp.

Dentinoenamel junction Interface of the enamel and dentine of the crown of a tooth.

Diagenesis Postmortem physical and chemical changes to bone.

Diaphysis The shaft of a long bone between its proximal (toward point of articulation) and distal (away from point of articulation) ends.

Enamel prism Basic structural unit of the enamel extending from the dentinoenamel junction to the surface of the tooth.

Foetal Embryo from the eighth prenatal week to birth.

In situ Original place of deposition.

Osseous Bone tissue.

Osteon The primary cellular unit of cortical bone.

Perimortem At (or around) the time of death.

Perinate Around the time of birth; 24 weeks gestation to 7 postnatal days.

Plexiform bone Horizontal regular layers of cells in mammalian cortical bone.

Postmortem Following death.

Subadult Age range encompassing nonadult (nonskeletally mature) individuals (also known as juvenile).

Taphonomy The study of postmortem processes affecting a body after death.

Trabecular bone Light and porous bone with a honeycombed or spongy appearance creating a latticework that is filled with bone marrow (also known as cancellous bone).

Trochanter Points of muscle attachment on the upper femur.

Vertebrate An animal that has a backbone or spinal column.

Introduction

Distinguishing human from nonhuman bone is a critical initial step in the forensic investigation of remains and confirmation or exclusion will direct the investigation. If human, analyses may include, but is not limited to, formulating a biological profile, that is, sex, age, stature, and ancestry, estimation of postmortem time, and contributing to the pathologist's determination of a possible cause and manner of death via the interpretation of perimortem skeletal pathology.

Preferably, a forensic anthropologist will process the discovery scene. This provides an *in situ* opportunity to examine context, estimate whether the remains are actual bones, and evaluate origins. An array of nonosseous objects including rocks, roots, and plastics can mimic bone in a variety of contexts. An onsite diagnosis of human or nonhuman prevents further time and financial investment. If skulls and/or teeth are present, then confirming or refuting human origin is not usually very difficult. There are, however, instances in forensic cases where recovered skeletal material includes only postcranial bones (either whole or fragmentary) and identification is required as to whether they are human, nonhuman, a mixture of both, or nonanimal. Postcranial bones of humans are similar in number to those of other mammals and even other vertebrates; the differences are in overall and relative sizes and in the presence of some structures (e.g., third trochanter in some nonhuman primates).

Forensic anthropologists draw upon their knowledge of human anatomy and osteology in conjunction with vertebrate osteology of species common to specific geography to help determine human from nonhuman. This relatively straightforward, noninvasive, macroscopic approach to bone and tooth assessment may not always confirm or refute species origins, especially if it involves bone reduced by burning, fragmentation, cortical loss, and, typically characteristic of such specimens, a combination of these effects. Hence, histological or molecular methods, though destructive, may be necessary.

We discuss how skeletal remains are commonly referred to the forensic investigator and how some biofunctional differences account for human and nonhuman skeletal variation. We also explore the key concepts underlying selection of the most appropriate method, given the condition of the remains, for example, degree of completeness and available resources. The main focus of the article, however, is to provide exposure to the methods available to the forensic anthropologist for diagnosing human from nonhuman bone.

Discovery of Skeletal Remains

Unidentified bones and objects are eventually transferred to the forensic investigator via the medical examiner, coroner, or other medicolegal official specific to a given jurisdiction. The exact proportion of human to nonhuman material discovered annually is highly variable and influenced by numerous

extrinsic factors, for example, size of the jurisdiction, urban or rural setting, local geography and fauna, and public sensitivity to such discoveries. In Knox and Anderson Counties in East Tennessee, ~30% of the cases examined are nonhuman remains. This frequency has steadily grown during the past quarter century, given heightened public awareness of the forensic significance of skeletal remains from media bombardment.

There is a diverse array of situations bringing remains to the attention of a forensic anthropologist. Nonhuman 'animal' habitation areas are frequently discovered by hunters, hikers, bushwalkers, and spelunkers and even during search and rescue operations for missing persons. This is common during the cooler months of the year when these activities are performed in areas not travelled during the warmer months. When hunted animals are butchered outdoors, parts become treats apportioned to dogs. Parts lacking meat or cleaned of muscle after butchering include long bones, joints, hooves, and paws.

To the untrained, the bones of bear (*Ursus*) paws are strikingly similar to human hand bones. In Australia, the bones of various kangaroo (*Macropus*) and sheep species (*Ovis*), amongst others, can be introduced in a similar manner. Only a fraction of the people making these discoveries would possess the knowledge to distinguish between human and nonhuman origin. Beyond skulls, the accuracy of the untrained observer drops significantly with postcranial bones and becomes virtually impossible when bones are fragmented.

Other potential scenes with human and nonhuman remains include motor vehicle and aircraft accidents, residential and commercial fires, and natural disasters. Here, it is not uncommon for pets and wildlife to become commingled, fragmented, and/or calcined alongside the human skeletal assemblage. Also, it is not uncommon for bones to be uncovered during earth-moving operations while digging foundations at utility and industrial sites. In Western Australia, urban renewal, in addition to residential expansions, has resulted in the discovery of nonhuman skeletal remains as food refuse.

Bone Morphology and Function

A well-established axiom in vertebrate paleontology points out that bone form is intimate with biomechanical function. This relationship intertwines form with the most fundamental movement, that is, locomotion, feeding behavior, etc. Alongside rote morphological species recognition, the principles of form and function underlie many of the methods that anthropologists and zoologists apply to distinguish isolated and fragmentary human and nonhuman mammalian vertebrate specimens. The uniquely human pattern of bipedalism is mentioned in regions of the skeleton, making it distinct when compared to skeletons of nonhuman quadrupeds.

Human locomotion is plantigrade, meaning the entire sole of the foot contacts the ground with each stride. Balance and support of the body's weight requires robust, irregularly shaped tarsal bones and elongated metatarsal bones. This tarsal-metatarsal arrangement forms the longitudinal and transverse arches of the foot which, along with select joints, provide foot strength and mobility and also act as a lever. Dogs, pigs, and other four-legged critters have digitigrade locomotion, walking with only toes contacting the ground. This movement requires elongated tarsal and metatarsal

bones, termed metapodials, which, compared to humans, are reduced in number and have functionally become the limb bone, lengthening it for increased stride length during running. These behavioral distinctions are not only reflected in the size and shape of the gross bone anatomy but also in the histological and molecular structure of the tissue. Hence, the relationship of form to function is an elementary characteristic that enables the anthropologist to diagnose human from nonhuman remains.

Method Selection

The majority of evaluations are successful through examination of gross morphological features, attainable with complete or substantial portions of diagnostic surface bone. The loss of diagnostic features and degree of fragmentation or cortical damage, loss, or weathering will determine the appropriate analytical method, for example, histological or molecular. Very often, method choice is linked to the cause and/or manner of death and/or postmortem taphonomy.

Another crucial aspect during gross evaluation is the biological age of the victim. Subadult bones, especially fetal and perinate, often bear faint resemblance to their adult counterparts and are frequently dismissed as nonhuman. Hence, it is imperative that the observer has a thorough and comprehensive understanding of the structural appearance of human skeletal and dental elements at all stages of growth. Such knowledge is assimilated after years of training and 'hands-on' experience, and although textbooks on juvenile osteology are an invaluable source, in isolation they do not provide sufficient demonstrations of the morphological complexities of nonadult bone.

For secure identifications when isolated fragments or calcined or cremated remains are discovered, assessing human or nonhuman origin will require either a histological approach in quantifying patterned cellular differences or immunological tests and DNA analysis at the molecular level. These methods too have their inherent shortcomings that limit their widespread utilization, including young age with the appearance of plexiform bone, sex, pathology, for example, osteoporosis affecting cortical bone, diagenesis obliterating structural arrangement, contamination, and diverse results from sampling design. Irrespective of all this, these nonmorphological methods require appropriate expertise and specialized laboratory equipment. To this end, there need to be some a priori inference that human remains are potentially involved.

Methodologies

Gross Skeletal Morphology – Macroscopic

An experienced osteologist can expeditiously ascertain human from nonhuman complete adult or subadult bones based on size and shape. Similar recognition applies to portions and fragments if they contain familiar diagnostic features such as joint articulations and muscle attachment sites (see [Figure 1](#)). The osteologist recognizes surface landmarks that relate to biomechanical function. Diagnosing an unidentified specimen involves deciding whether the bone(s) lies outside the range of

Figure 1 Comparison of human to commonly discovered nonhuman right anterior tibiae. All specimens are adult with the exception of the kangaroo being adolescent. Besides representing commonly discovered vertebrate species in forensic contexts, these bones demonstrate the relative variation in gross features between the species, including size, shape, joint articulations, and muscle markings (centimeter scale).

human morphology while taking into account age, sex, ancestry, and antemortem pathology. Whole skulls and postcranial bones are not problematic to identify. However, fragmentary specimens from any region of the skeleton present challenges.

While law enforcement may be slightly embarrassed, though relieved when a 'nonhuman' diagnosis is achieved, species recognition of the nonhuman bones may be desirable. Not all osteologists performing forensic identifications have training and access to comparative faunal collections of multiple vertebrate species, particularly those outside their geographic range. Such skeletal collections are a valuable resource for differentiating human from nonhuman bone. These collections are accessible in museums or vertebrate osteology collections in university anthropology and/or zoology departments. Quality reproductions of numerous extant species are available through France Casting® and Bone Clones®.

Where comparative bone is unavailable, bound atlases and CD versions of vertebrate skeletal anatomy are valuable. These were initially developed for archaeologists and zooarchaeologists examining archeological bone, but recent editions are styled for forensic applications. Recent atlases provide images and descriptions of juvenile and adult nonhuman bones commonly encountered. Standard views of most bones highlight the most relevant distinguishing features and describe potential variations related to sex, age, and pathology. Most of these recent atlases focus primarily on North American fauna. Forensic practitioners examining unique indigenous fauna from other continents should consult regional published sources and zoological journals.

The teeth reveal more about life than any other vertebrate tissue. At both gross and histological levels, mammalian teeth are species specific and one does not have to be a dentist or a dental anthropologist to immediately recognize an unfamiliar whole tooth (see [Figures 2](#) and [3](#)). Current

Figure 2 Buccal view of the mandibular left first molars among commonly discovered vertebrate species from forensic contexts. Note the crown and root size and contour differences between, starting at left, human, deer, dog, pig, and cow (centimeter scale).

Figure 3 Occlusal view of the mandibular left first molars among commonly discovered vertebrate species from forensic contexts. Note the differences in cusp size, shape, and arrangement between, starting at left, human, deer, dog, pig, and cow (centimeter scale).

palaeoanthropological research assesses speciation and dietary trends in cuspal gross morphology and the microstructural nuances of enamel prism and dentine patterning. At the forensic level of morphological interpretation, there are several atlases which provide an appreciation of teeth in the comparative format.

The orofacial structures are particularly vulnerable to blunt force impacts and breakage with fragmentation and dissociation from the body. Fracture with separation and distancing may be enhanced in an extended postmortem interval between death and discovery and result in skeletonization. Hence, the forensic anthropologist, with adequate training, immediately recognizes whole teeth as human or nonhuman and similar to pieces and fragments of bone, there is an inverse relationship between tooth fragment size and species recognition. Yet, like vertebrate bone, mineralized tissues from the orofacial region, including the alveolus, root dentine, and enamel, are histologically distinct from one another and between species (see [Figures 4](#) and [5](#)). The smaller the specimen, the more problematic the identification and the more necessary a histological approach. Histology is a remedy for troublesome pieces and fortunately, dental fragments typically contain alveolar bone with roots and crown parts attached.

Gross Morphology – Radiographic

Comparative osteological collections and/or atlases are helpful in the identification of whole bones or fragments with macroscopic diagnostic features. Diaphyseal fragments alone, especially the midshaft, are less reliably identified macroscopically, although morphometric methods are being developed. With fragments, differentiation between human and nonhuman animals is possible by evaluation of cortical thickness and internal trabecular patterning.

Figure 4 Light micrograph of human dental enamel $\times 100$ showing simple enamel prism structure. The dentoenamel junction is at the upper left of the image.

Figure 5 Light micrograph of domestic horse dental enamel $\times 100$ showing exuberant, though a patterned, enamel prism structure. The dentoenamel junction is at the lower left of the image.

Cortical bone thickness is greater in nonhuman animals, which can be recognized. Radiographic features are common in the nonhuman diaphysis, including nutrient canals with medullary extensions, more dense and homogenous trabecular bone and a sharp transition between cortical and trabecular regions. Some of these features may be observable in larger fragments not requiring radiography. However, if non-diagnostic, fragments require specialized destructive methods.

Histology

In bone fragments lacking species-specific macroscopic surface features or radiographic specifics, a histological evaluation is required. Visual and quantifiable metric analyses can discern pattern differences in the microscopic arrangement of human and nonhuman bone (see [Figures 6](#) and [7](#)). The most obvious differences are in limb cortices which are directly related to the aforementioned functioning. Plexiform cortical bone is commonly found in nonhuman mammals, characterized by osteons arranged in regular horizontal layers. This rectangular

Figure 6 Nonhuman (deer) plexiform bone at $50\times$. Note the rectangular block pattern and distinct structure different from human bone at the same magnification.

Figure 7 Human osteonal bone at $50\times$. Note the random overlapping circular pattern.

pattern is rare in humans, with the possible exception of developing fetal and younger subadult bone.

Microscopically, human bone is termed osteonal or Haversian, and has a central canal surrounded by concentric rings. This arrangement allows vascular and nervous nourishment of the cortices. Human osteons have a true circular appearance and are arranged in randomly overlapping configurations. Osteons in nonhuman animals also have a uniform circular shape, though with more regularity. In humans, replacement or 'secondary' osteons develop during modeling and remodeling; also, the dimensions of the osteon, its Haversian canal, and other features of the tissue are significantly larger than those in cow, pig, sheep, horse, dog, and rabbit.

After proper orientation of the convex cortex and concave medullary surface of an unidentified midshaft, the fragment is embedded in an epoxy medium and cross sectioned at $\sim 100\mu\text{m}$. The most consistent results are obtained from adult long bones as opposed to irregular or flat bones or newborn and subadult specimens. Undecalcified ground

sections are the simplest to manufacture and diagnostic success is equal to more difficult sectioning protocols.

After grinding and polishing, sections are examined at $40\times$ – $200\times$ magnifications using a compound light microscope. And while light microscopy adequately performs the diagnostic identification work, scanning electron microscopy (SEM), though cost-prohibitive, more clearly elucidates pathological and/or diagenetic alterations. The structural characteristics can be qualitatively assessed with confirmation or refutation of human origin.

Quantitative visual inspection affords a degree of statistical confidence in assessments. Depending upon the level of jurisdiction, for example, state or federal, this may be mandatory for admissibility in court. Osteonal measurements can be obtained using a variety of methods. Thin sections, generally visualized at around $200\times$, are captured and imported into a software package, allowing direct measurement. Those measurements can be compared to species means or used in specific two-group (in this case human and nonhuman) or multiple-group discriminant functions. The former is designed to discriminate between human and nonhuman origin, while the latter provides species identification. Smaller osteonal dimensions are generally found in smaller animals. Data taken from published literature show that the mean maximum diameter of a human femoral secondary osteon is approximately $264\text{ }\mu\text{m}$; corresponding figures for rabbit, sheep, pig, and cow are 131, 206, 211, and $270\text{ }\mu\text{m}$, respectively.

When evaluating forensic human or nonhuman bone(s), it is unlikely that species identification beyond those two groups is necessary. However, the ability to make a species-level estimation is valuable to the database of forensic standards. The degree of expected classification accuracy for histomorphometric discriminant analyses is between 76% and 83%. One factor that has not received due research attention is the degree of intra- and interobserver error in osteon measurements; this has potential ramifications for evidence under legal scrutiny. Importantly however, the degree of uncertainty in the final determination is quantified.

Molecular – DNA

The development of DNA profiling technology has revolutionized forensic practice, and its applications are widespread and clearly cross-disciplinary. With respect to the identification of unknown human skeletal remains, DNA profiling is a core method of obtaining a positive identity, especially in the absence of antemortem dental and medical records. There are numerous other applications of DNA technology relevant to the forensic anthropologist, including sex estimation, ancestry informative markers, and familial relationships. It is also possible to distinguish human from nonhuman bone on the basis of DNA sequences. It is important to note that the feasibility of undertaking such analyses may be restricted in routine forensic anthropological casework given the expense, equipment, and expertise required, not to mention the destructive sampling technique. Regardless, it is possible to analyze DNA markers for species identification.

The species to which an unidentified bone sample belongs can be determined through the analysis of species-specific DNA sequences. Hence, by determining species origin, this

technique provides insight beyond answering whether the remains are human or nonhuman. These distinctions may be crucial in cases involving poaching of endangered species or ritual animal sacrifice. In distinguishing human from nonhuman tissue, the analysis of mitochondrial DNA is generally preferred compared to examination of nucleic DNA. Mitochondrial DNA contains a high copy number within cells, so it is more likely to yield a useable profile from degraded bone.

To avoid contamination, a bone specimen for DNA analysis needs cleaning and decontamination. Several protocols are popular. After decontamination and preparation, the sample is drilled or sectioned, depending on the amount of destructive sampling allowed. The bone is then decalcified in an EDTA or Chelex[®] suspension and protein digestion is performed using extraction buffers. Following DNA extraction, PCR amplification, DNA sequencing, and analysis are performed. Human DNA is distinguished from nonhuman on the basis of species-specific base changes. If nonhuman animal species identification is sought, species-specific primers that only produce a PCR product with the animal species for which they are designed are commercially available. It is important to note that it may not be possible to extract and amplify DNA from highly degraded, burnt, and/or contaminated specimens and in these instances an immunological approach may be more feasible.

Molecular – Radioimmunoassay

There are instances when both histological and DNA analyses of nonmorphologically distinct bone fragments is unable to resolve the human origin. This may occur because the microscopic arrangement of all regions of human bone is not mutually exclusive to all vertebrate species or it could be due to burning and extreme fragmentation. Solid-phase radioimmunoassay (pRIA) techniques offer a promising alternative approach toward confirming or refuting the human origin of even the smallest fragments of bone on the basis of protein collagen detection. The development of pRIA techniques took place in the field of molecular evolution to examine relationships of fossil species. Recently, its forensic applicability has been championed through robust collaborative research by a select group of anthropologists and molecular biologists.

Sample preparation involves removing surface contaminants and, depending on the bone type, drilling to a depth of 2 mm to acquire noncontaminated material. An ethylenediaminetetraacetic acid (EDTA) solution is typically used for dissolution of the bone powder to isolate protein. Following dissolution, the protein in the EDTA solution is bound to plastic discs, which is termed the 'solid phase' aspect of the technique. The remainder of the process, taking at least 48 h, involves the addition of species-specific polyclonal antisera and other radioactive antibodies. The antisera are produced specifically for human and many nonhuman species, including sheep, dog, bear, and chicken. The binding of specific antisera to specific antigens is quantified to determine the species.

Blind tests of radioimmunoassay approaches have yielded 100% accuracy in discriminating human from nonhuman origin. Only a very small amount of bone, on the order of $\leq 200\text{ mg}$ to 1 g is required. It is important to note that some immunological techniques, like inhibition ELISA to detect human albumin, may still be viable in cases where DNA is

poorly preserved but the associated protein epitopes have maintained their informative characteristics. Histomorphometric approaches, however, can be effectively applied to calcined bones lacking quantifiable DNA. The inclusion of radioimmunoassay methods in mainstream forensic anthropology is limited due to the advanced expertise and costs involved.

These results are limited in independent testing of the method for forensic remains in corroboration to the excellent results received in the original research. Validation of the power and utility of this technique has been established pertaining to evolutionary relationships of various fossil species. On these grounds, this should be considered a method of choice in situations involving extreme fragmentation and/or especially where bones are burned or altered to the point where quantifiable DNA cannot be retrieved.

Summary and Conclusions

Accurate identification of the human origin of even the smallest of bone fragments is a crucial initial step in a forensic investigation involving skeletal remains. As discussed, the appropriate method is related to many factors, which include the degree of representation, preservation, and whether destructive sampling is permitted. A variety of methods are available and although all potentially offer positive identification, their utility is not without specific limitations. They include expertise, specialized equipment, and the cost and time necessary to employ the technique. The exceptions are instances in which assessment is performed through the examination of gross morphological features and obviously this is the preferred method for the confirmation or exclusion of the human origin of unidentified skeletal remains.

Glossary

Discriminant functions Algebraic expressions used to determine which continuous variables/characteristics discriminate between two or more naturally occurring groups/populations.

Geometric morphometrics A technique that is used to study the mathematical and statistical properties of shape, based on three-dimensional landmark data.

Gonial eversion The outward flaring of the gonial region of the mandible, which is said to be often present in males.

Greater sciatic notch The deep indentation on the posterior border of the pelvic bone that occurs at the union of the ilium and ischium.

Morphology The study of the shape and structure of an object or organism, in this case a skeletal element.

Osteometry Anthropometric measurement of the bones belonging to the human skeleton.

Preauricular sulcus The groove on the surface of the ilium, lateral to the auricular surface that is often more pronounced in females than in males.

Robusticity The degree of robustness expressed through the diameter or circumference of a bone in relation to its length.

Sectioning point A statistical line that provides insulation between adjacent sections without disrupting the current continuous collection.

Sexual dimorphism Morphological differences between males and females of the same species.

Univariate discriminant The distribution of a single variable/characteristic in a population or species.

Introduction

Assessment of sex is extremely important when it is necessary to establish identity from skeletal remains. In the first place, this classification effectively cuts the number of possible matches in half, and proper identification could never be made if officials were told to look for a male when the remains were actually those of a female. Moreover, other analyses such as estimation of stature cannot be correctly done as the sex of the individual must be known in order to select the correct formula. Thus, isolating, interpreting, and quantifying the manifestations of sex are an essential part of all skeletal analyses. Unfortunately, this is often not a simple process as male and female attributes span a continuum of morphological configurations and metric measures in the skeleton. Although some bones are better indicators than others, there is no skeletal feature that rivals the definitiveness of differences between fleshed individuals.

In some cases, remains of clothing, hair, jewelry, and other artifacts may be helpful to corroborate a skeletal assessment and indeed lead to a positive identification of the items in question, but they may also be misleading. One must be particularly careful in mass disasters where both bones and personal items may be commingled. Therefore any identification should always be corroborated by an assessment of the skeletal remains.

Sexual Dimorphism

In normal, living humans, sex is a discrete trait determined by the genotype and diagnosed by observing one of only two possible morphological features. These differences (e.g., external genitalia) are apparent at birth and clearly recognizable even during the prenatal period. In the skeleton, however, the most effective sex

indicators do not begin to develop until adolescence, and some are not fully expressed until adulthood. Therefore sex estimation in children remains problematic, and even with a complete adult skeleton available for assessment it may not always be possible to arrive at the correct estimate in all cases.

There are two methodological approaches to sexing skeletal remains: morphological and metric. Morphological techniques focus on shape – the bony configurations that are macroscopically visible and differ between males and females. There are important advantages to this approach, especially when a particular form is recognizable despite temporal and population variation. Obvious morphological differences such as those observed in the pelvis of an adult may allow optimal separation of the sexes (approaching 95% accuracy). The main drawback of the morphological approach in general (especially when judgment of size is involved) is that it is based on ‘eye balling,’ so if the formation in question is not patently obvious, experience becomes an essential component. The observer must develop a sense of what is relatively large or small, angled or curved, wide or narrow. Intra- and inter-observer repeatability and statistical analyses of these features are also problematical, and it is difficult to assign a degree of confidence with which the estimate has been made.

In the past few years, geometric morphometrics has become a popular method with which to confirm and quantify observed shape differences. Using this method it is possible to observe in more detail exactly where the variations in shape occur, and what their magnitude is. Several software packages are available for this purpose, and all provide statistical data such as classification accuracies and level of significance of observed differences. It works well at the population level to assess and quantify differences, but remains difficult to apply to an individual forensic case, when sex estimation for only that specific individual is needed.

Not all skeletal components have consistent and discernible morphological evidence of sexual dimorphism. Problems arise when differences are only size based and there is no clear male or female shape, or where the remains are incomplete and the observer has to rely on less dimorphic bones. In these cases, a metric (size-based) approach is followed. The advantages of these methods are that they are easy to use and provide indications of the accuracy with which the estimation can be made. However, the overlap between the sexes, along with significant population variation, creates some problems. These metric analyses are based on bone dimensions and are the methods of choice for skeletal parts like long bones that do not exhibit clearly definable shape variants. Often a combination of measurements is selected from each bone to maximize sex diagnosis using discriminant function statistics. The major problem with this technique is that standards are temporally sensitive and population specific (both between and within groups) – a formula for African Americans may not work on black individuals from southern Africa. This approach draws heavily on the fact that males tend to be more robust because normal testosterone levels produce greater muscle mass, but cultural variation in functional demands may lead to both differences in the expression of sexual dimorphism and its magnitude. This is of concern in bones where dimorphism is not primarily developmental, that is, those that reflect weight-bearing and labor-intensive stress.

The diagnosis of sex from the skeleton is further complicated by a number of diverse factors ranging from environmental influences and pathological conditions to secular trend, diet, and occupational stress. All skeletal sites and traits are not equally effective at distinguishing one sex from the other. So the question arises – why bother with the less definitive parts? The answer is simple – skeletal remains are rarely complete and undamaged, even in recent forensic cases. Therefore, the investigator must be able to glean as much information as possible from any bone or fragment. This article presents an overview of current methods and their accuracy for sex determination from the human skeleton.

Sex Estimation in Subadults

Because sex differences in the immature skeleton are not readily observable before puberty, the few attempts that have been made to look for dimorphic indicators have met with limited success, especially for individuals in the first few years of life. This problem is confounded by the fact that very few well-documented skeletal collections with large numbers of juvenile skeletons are available, making it very difficult to develop and test methodology.

A number of differences in the pelvis have been studied, among them the elevation of the auricular surface, angle of the greater sciatic notch, depth of the sciatic notch, curvature of the iliac crest, and the 'arch criteria' at the auricular surface. In general, the association of these traits with a specific sex becomes more pronounced with age, and relatively poor results are found in individuals below two years of age. Using these criteria, some researchers have reported success rates around 80% in slightly older children, whereas others caution against their use in a forensic setting.

Several studies have also been done on the development of sexual dimorphism in the mandible, and aspects such as the shape of the inferior symphyseal border and corpus, gonial eversion, mandibular protrusion, mentum shape, and mandibular arcade shape have been assessed. Once again, conflicting success rates have been reported. It seems that the expression of these traits may vary throughout the childhood years and may also vary between populations. The same can be said for differences in orbit shapes, robusticity of long bones and the basicranium. These methods may all be used in an attempt to estimate the sex of an unidentified subadult, but should be used with caution and only by a trained individual who has experience with the specific method. It should also only be used in a population for which that method has been tested.

Attempts to capitalize on sex differences in the size of both the deciduous and permanent dentition have been somewhat more successful. Tooth dimensions (length and breadth) do vary between the sexes, but a large degree of overlap exists so that it is difficult to use this in individual cases. Formulae developed on the basis of permanent teeth of adults may also not necessarily be valid for juveniles, as selective mortality or cultural bias may increase or decrease the level of sexual dimorphism closer to adulthood. Tooth size varies between populations, but discriminant function formulae are available for a number of populations and may be of use in those specific regions.

In a recent study, the nonmetric characteristics of the distal humerus were used to estimate sex in adolescents. The four characteristics used were trochlear constriction, trochlear symmetry, olecranon fossa shape, and angle of the medial epicondyle. The expected male/female differences are shown in [Figure 1](#). This method has been tested in adults as well. In a study of 42 adolescent distal humeri, an average accuracy of 81% was obtained. These results look promising, but still need to be repeated by other researchers.

The Adult Skeleton: Morphology

When the morphological expressions of sexual dimorphism in the adult skeleton are easily distinguishable, they provide a reliable means of diagnosing sex. Traditionally the pelvis and skull have been used for this purpose, whereas other bones such as the humerus, scapula, and proximal femur may also show some shape differences.

The Pelvis

The pelvic girdle is composed of three bones: two coxal (or hip) bones and the sacrum ([Figure 2](#)). Each hip bone is in turn the product of the fusion of three bones: the ilium, ischium, and pubis. The female pelvis is designed to accommodate childbirth whereas the only requirements for males are support and locomotion. These differences manifest in various parts of this complex structure. [Table 1](#) summarizes the morphologic differences in the pelvis.

The most easily assessable morphological feature is the subpubic angle formed by the ventral articulation of the pubic bones at the symphysis ([Figure 2](#)). The male pelvis is characterized by roughly triangular pubic bones that form a

Figure 1 Morphological differences in the distal humerus (Male, left; female, right).

narrow subpubic angle. Pubertal growth modifications in females are centered on the facilitation of childbirth. Elongation of the pubic bones creates a more rectangular shape and results in a much wider subpubic angle and larger outlet. Further enlargement of the pelvic outlet is accomplished by widening of the greater sciatic notch in females, but this feature may show considerable variability and is sometimes difficult to assess. It also shows some variations in expression between different populations. If the sacrum can be articulated, it gives a much clearer picture of the width of the notch by completing the dorsal portion. Other female adaptations which can be used in sex determination include a rounded (as opposed to the heart-shaped male) inlet, a dorsally

orientated tilt of the sacrum, and a small and everted ischial spine. The upper section or 'false pelvis' is broader and deeper in males, whereas the lower portion or 'true pelvis' is wider in females. The ischial tuberosity is positioned more dorsally in males and laterally in females. A uniquely male trait is the rough everted area of the medial border of the ischiopubic ramus for the attachment of the crus (corpus cavernosum) of the penis. This ramus is more gracile in females and narrows as it approaches the symphysis. In the sacrum, females show a proportionally smaller superior articular surface relative to the total width of the wings.

If a well-developed preauricular sulcus is present, this also indicates a female individual. This sulcus usually develops

Figure 2 Sex differences in the pelvis.

Table 1 Morphological sex differences in the pelvis

Trait	Male	Female
Pubic symphysis	Higher	Lower
Pubic bone shape	Triangular	Square or rectangular
Ventral arc on pubis	Absent	Present
Subpubic angle	Narrow, V-shaped	Wide, U-shaped
Acetabulum	Large, laterally directed	Smaller, anterolaterally directed
Greater sciatic notch	Narrow, deep	Wide, shallow
Ischiopubic rami	Rough everted margin	Gracile, narrows near symphysis
	Broad medial surface	Ridge on medial aspect
Sacroiliac joint	Large	Small, oblique
Postauricular space	Narrow	Wide
Preauricular sulcus	Rarely present	Often present
Iliac tuberosity	Large, not pointed	Small or absent, pointed or varied
Sacrum	Long, narrow, and straighter	Short, broad, marked curvatures
Pelvic inlet	Heart shaped	Circular, elliptical

after a pregnancy, and is caused by stress on the sacroiliac ligament. Extensive scarring on the posterior (dorsal) side of the pubis, such as dorsal pitting, may also be the result of pregnancy and labor.

As in all skeletal remains, the most diagnostic parts are not always available, especially following extended periods of

exposure to the elements or years of burial. Since spongy bones are more prone to destruction, highly dimorphic bones like the pubis may not be available for diagnosis.

The Skull

Sex differences have been investigated in nearly every feature of the skull. **Table 2** contains a list of dimorphic cranial characteristics (**Figure 3**). In general, the male skull is expected to have more rugged sites of muscle attachments, a prominent glabellar region, and thicker bones. A large, pronounced supraorbital torus and rugged occipital protuberance can be considered reliable male characteristics. When viewed laterally, the sloping male forehead gives the vault a more rounded outline than that of the relatively vertical female forehead. Males have larger mastoid processes. Both frontal and parietal eminences tend to be better developed in females. Some differences in the cranium are of a proportional nature such as the orbits. Because eyes are of similar size in both sexes, the orbits appear to take up a larger portion of the face in females. Females also tend to have round or square orbits with sharp superior orbital margins, in contrast to the more rectangular orbits with rounded margins in males.

One of the most dimorphic parts of the skull is the mandible. If only the symphyseal region of the mandible is present, a squared or undercut base is often associated with males and a round or pointed inferior outline with females. Initial research on the ramus of the mandible indicated that flexure in this area is associated with males; however, subsequent research yielded conflicting results. Geometric morphometrics, in particular,

has shown that this is not a consistent shape difference that can be used with a high level of accuracy to distinguish between the sexes, although other independent morphological studies have shown some success with this method. The same can be said for gonial eversion, which seems to be unreliable for sex

estimation. In general, the male mandible is more robust, with a broad ramus and well-developed chin area.

In all skeletal assessments, it is important to remember that humans vary both temporally and spatially. To this one may add variation arising from growth factors, environmental stress, and pathology or trauma. Therefore, small or absent brow ridges or prominent eminences are not necessarily female indicators. The same can be said of a rounded chin and a less rugged occipital region, both of which are not uncommonly seen in males. In this regard, population differences are a major cause of variability in the expression of sexual dimorphism.

Table 2 Morphological sex differences in the skull

Trait	Male	Female
General appearance	Rugged	Smooth
Supraorbital ridges	Medium to large	Small to absent
Mastoid processes	Medium to large	Small to medium
Occipital area	Prominent muscle lines and protuberance	Muscle lines and protuberance not prominent
Frontal eminences	Small	More prominent
Parietal eminences	Small	More prominent
Orbits	Rectangular, relatively smaller	Round, relatively larger
Orbital margins	Rounded	Sharp
Forehead	Sloped	Vertical
Palate	Large, broad, U-shaped	Small, parabolic
Mandible	Robust, broad ramus	Gracile, narrower ramus
Mental eminence	Large	Smooth, small eminence
Teeth	Large, lower M1 more often 5-cusped	Smaller, molars often 4-cusped

Other Postcranial Indicators

A number of papers have been published outlining differences in the morphology of especially the distal part of the humerus. Sexual dimorphism in this area is said to be due to differences in the carrying angle of the articulated humerus, radius, and ulna. In adults, accuracies ranging from 74% to 94% have been reported for various populations when combinations of characteristics demonstrated in Figure 1 are used. These differences have also been elucidated by means of geometric morphometrics.

Similarly, geometric morphometrics has been used to outline differences in the shape of scapulae and orbits between males and females, with high rates of accuracy in separating the sexes. These results need to be tested in various populations, also making them practically applicable when assessing single skeletons.

Figure 3 Sex differences in the skull.

The Adult Skeleton: Metric Analysis

Osteometric analysis generally yields high levels of accuracy for the diagnosis of sex. Techniques range from the calculation of a simple sectioning point derived from a single measurement to complex multivariate discriminant function analysis. Indices formed by the relationship of one dimension to another, such as that of the ischiopubic index, allow male/female comparisons while eliminating size as a factor.

Discriminant function analysis is one of the most commonly used techniques to develop sex determination formulae using one or more measurements from the skeleton. Discriminant function formulae have been developed for almost all bones of the postcranial skeleton, for a wide range of populations across the world. Generally, the formulae for the larger long bones such as the femur and humerus provide the best results, whereas those for smaller bones such as the bones of the hands and feet perform less well. Usually tables are published with unstandardized coefficients, which should be multiplied with the measured values of the specific bone. Within one specific formula these should be added together, along with the constant. Values higher than the sectioning point usually indicate a male individual and vice versa, and percentages are given to indicate the accuracy with which the individuals from the original population were classified.

In general, selection of dimensions for a formula depends on levels of intercorrelation as well as the degree of difference between the sexes. It is, for example, very likely that femoral distal breadth is significantly correlated with tibial proximal breadth and therefore one of these may suffice to provide the best result. In the major long bones, it has been observed that epiphyseal measurements are better indicators of sex than length or diaphyseal dimensions, and accuracies are fairly high. With this in mind, univariate discriminant functions were calculated using eight single dimensions from the humerus, femur, and tibia (Table 3). Although most of the dimensions used are standard measurements (clearly defined in major reference books) these dimensions were also selected because these segments of the skeleton are commonly recovered, even when the skeleton is badly fragmented. In order to make this methodology applicable to diverse populations, osteometric analyses of modern (twentieth century) skeletal samples have been conducted on US whites and blacks, South African whites and blacks, and Asians, including mainland Chinese and Japanese. Table 3 lists descriptive statistics for males and females along with the average of the two sexes (sectioning point) and percentage accuracy. In all samples, males were significantly larger than females. Using this technique, determination of sex is accomplished by comparing the dimension of an unidentified bone with the sectioning point for that population. For example, if the humeral head diameter of an unidentified American white is 47 mm, classification would be 'male' (any value larger than 45.6 mm classifies a person as male in this group). Although overall accuracy is 84.8% (Table 3), the farther the measurement is from the sectioning point, the greater the likelihood of correct sexing. Moreover, if the humeral head diameter is greater than the male mean (48.6 mm) or less than the female mean (42.6 mm), the probability of correct determination would be much higher. It must be emphasized, however, that it is

necessary to know ancestry in such cases, unless the values of the unidentified specimen are extreme.

As noted earlier, metrics are group specific, except probably for the pelvis. As is evident from Table 3, populations differ from each other in the degree and range of dimorphism exhibited by various dimensions. This reflects differences in both size and proportions. In general, South African whites are the largest of the groups assessed, whereas South African blacks are among the smallest, with a mean closer to that of the Chinese and Japanese. Table 3 also reveals population differences in the locus of dimorphism. For example, femoral distal breadth is the most diagnostic measurement in South African whites, whereas maximum dimorphism in the Japanese is found in the epicondylar breadth of the humerus.

FORDISC 3.0 (FD3), which is distributed by the University of Tennessee, is an example of an analytic program that employs discriminant function analysis to assist in assessing sex, ancestry, and stature from unidentified skeletal remains. With the measurements entered from the crania or postcranial remains, discriminant function formulae are created on the fly. Statistical output includes group membership, cross-validated classification accuracy, posterior probabilities, and typicalities. Posterior probabilities are calculated to provide information on group membership, based on the distance of a group to each of the other groups, whereas typicality (F , Chi , and R) probabilities represent the likelihood that an unidentified part belongs to the group to which it has been assigned. Authors of the program strongly caution against using the software if the population that one is examining is not represented in the database.

Summary and Conclusions

Although there are many techniques to determine sex from practically every part of the skeleton, there are a number of caveats. The accuracy of both morphological and osteometric sex assessment depends on rigorous training and first-hand experience in observing skeletal remains. The overlap between the sexes implies that structures show gradations of differences within and between sexes and populations. This gradation must be carefully evaluated by studying large documented skeletal collections from different regions of the world. Bone measurement is a tedious process and requires consistency and standardization. The technique has a long history and although there is international agreement among scientists on how measurements are taken (to allow comparability), individual variation in measuring and interobserver error are always troublesome factors.

Even though decades of research have resulted in a plethora of methods and standards of assessment, many factors complicate the determination of sex from the skeleton. Age must be considered because the skeleton does not exhibit maximum dimorphism until sexual maturation and growth are complete. It has also been shown that the degree of sexual dimorphism may change with advancing age and that especially osteoporotic females may show an increase in robusticity in old age. Problems also arise when one has only a partial or fragmented skeleton. It is not always easy to distinguish certain bones of a male of 17 from one in his 20s and as growth can continue into

the latter decade, sex differences may be clear neither metrically nor morphologically. This is further complicated by the fact that there is significant variation between populations who inhabit different geographic regions and constitute established gene pools.

Finally, since anything that affects the growth, development, maintenance, and remodeling of the skeleton can modify the expression of sexual dimorphism, trauma and disease can result in missexing. Some conditions cause abnormal bony enlargement whereas others result in atrophy or obliterate normally clear morphological differences. The intimate relationship between bone and muscle means that even in the absence of obvious damage to a skeletal component, muscular impairment

can lead to inappropriate remodeling. All of these factors, above and beyond the normally occurring variability, subtleness, and overlap of features in the human skeleton, make it essential that only properly trained and experienced forensic anthropologists be consulted in every case involving the medicolegal system.

Introduction

In the forensic context, aging the dead and aging the living have different goals. For the dead, it is identification: determining the age of a decedent helps create a biological profile, which can be compared to that of a missing person. For the living, it is to solve judicial problems: for example, aging a living person can help in cases of suspected pedopornography and when determining criminal responsibility and pensionable age for adults lacking documents.

Dental and skeletal methods are most commonly used for aging. There is no one aging method that is applicable and reliable for all individuals and for all ages, from neonates to the elderly, living and dead, although there are a variety of methods and combinations of methods available in the literature. There are several reasons for this.

- Very few methods are reliable in both the living and the dead.
- Different methods typically use different statistical procedures, which make results incomparable.
- The reference samples, on which the methods have been developed, are often too specific, making the method results dependent on the demographic and chronological profiles of the series.
- Many published methods have not been tested on diverse populations or in a variety of contexts and, therefore, cannot be used in forensic practice.

For both the living and the dead, the goal of aging is to determine physiological age, which might be quite different from chronological age. Consequently, the older the person is, the larger is the discrepancy between physiological and chronological ages, and the less accurate the methods are. As a result, aging a person (living or dead) is never a simple procedure and always needs a multistep approach, such as the one described below.

- First, determine the age category (or stage or phase) the person belongs to: subadult (0–20), transition phase (20–30), young and mature adult (30–55), or elderly (>55).
- Second, choose the method that provides the best results within the age category, taking into account the characteristics of the case (sex and ethnicity) and the practical conditions (state of the body for the dead and the available technologies for the living).
- The so-called reality principle, which takes into account the time required to provide an age and the cost of the method used to provide the estimation, must also be considered.

This article provides the reader with practical advice on choosing the right strategy for each type of aging case.

The Dead

Literature Review

This section does not review the literature in the archeological context, as this literature is almost useless for forensic purposes because the material it covers (different states of preservation, taphonomic effects, etc.) and its goals are very far from the judicial requirements (time, cost, and precision of evaluation). However, the article on aging in Ubelaker's classic textbook is widely used as the successive editions have moved from archeological to forensic concerns.

Determining Age Categories

Well-preserved remains

In well-preserved bodies, a simple visual external examination will allow the examiner to classify the decedent into a subadult, young adult, mature adult, or elderly adult.

Partially decomposed remains

In the autopsy room, basic x-rays (and the increasingly available CT scan) can provide valuable information about epiphyseal fusion and tooth eruption stages, as well as degenerative changes in bone and joints, all of which can help examiners identify an appropriate age category. x-Rays of the third molar, the sternal end of the clavicle, the hand, and the wrist can provide particularly valuable information.

Skeletonized remains

In skeletal cases, the size of the bones (especially the long bones) and the general appearance of the skeleton can provide enough information to allow the examiner to properly categorize the case. In fragmented remains, a more precise osteological study with measurements of length, width, and diameters of bones is necessary.

Methods by Age Category

Subadults (0–20)

Classically, subadults are divided as follows: fetus, newborn, infant (0–6 years), child (7–12), and adolescent (13–20). Whatever the method used, having a reference population with which the sample can be compared is of utmost importance.

- (a) *Fetuses*. As dentition is more reliable in aging fetal remains than skeletal development, one must first verify dental, and then skeletal, development. If crowns are present inside the crypts, x-rays should be performed and the Schour and Massler method, as processed by Logan and Kronfeld, should be used. When examining skeletal remains, the

data provided by Fazekas and Kosa on long bone development are largely used; Scheuer and Black's method is based on this method. Recent literature is attempting to validate these methods with updated radiographic data.

- (b) *Newborns*. In order to verify whether the fetus is full-term, one must check the following elements: the greater fontanel has to be open and the smaller ones should be in the process of closing or should be closed; the ossification of the distal epiphysis of the femur should be present; and mineralization of the tip of the cusp of the first permanent molar should be visible on x-ray. Diaphyseal length of long bones is not determinant (because of variation in body size), but one should measure tibia, femur, or humerus as a general indicator. Scheuer and Black's method can be used as well.
- (c) *Infants (0–6 years) and children (7–12)*. Tooth calcification and eruption are the methods of choice for aging the remains of infants and children, and have been calibrated extensively on mandibular and maxillary teeth. Several tables and charts, including the Schour and Massler charts and the Demirjian charts, exist. The Willems revisited method has shown the most reliable results, followed by the Demirjian method.

Skeletal development should also be assessed when aging the remains of infants and children. A comparison between dental and skeletal ages is always necessary in order to corroborate results (and verify possible discrepancies), as well as to look for indications of sex, as males have a delay in skeletal growth when compared with females. In infants, the examiner must check for the ossification of skull bones, mainly temporal, occipital, and frontal bones, as well as the mandible. In children, the examiner should consider long bone diaphysis, appearance of ossification centers, and the fusion of epiphyses. In these cases, the age estimation cannot be assessed without a comparison with tables from the correct reference population in order to reduce impact from racial and environmental factors.

- (d) *Adolescents (13–20)*. Demirjian's method can be used to age adolescent remains. The same general rules apply as for children; however, more specific and accurate information can be obtained by applying methods, which were devised for aging the living. For example, age estimation in adolescents can be assessed by evaluation of skeletal development of hand and wrist bones, by x-ray examination, and by comparison with the Greulich and Pyle atlas (GPA), Tanner–Whitehouse (TW) score, and FELS method. All methods have proved to give similar results and to be influenced by the racial characteristics and medical and economical development of the country to which the samples belong.

Transition phase (between 20 and 30 years)

This period spans adolescence to early adulthood. From an anthropological point of view, adulthood can be defined as the time when epiphyses are fused, indicating the end of bone growth. As a general indication, the end of adolescence can be checked through the fusion of thoracic and lumbar vertebral rings, and iliac crest with x-ray examination by Risser staging. The iliac crest of the ilium begins to fuse with the ilium

Table 1 Recommendations concerning age estimation methods for remains of adolescents and subjects in transition phase; standard errors go from 0.5 to 2 years

<i>Adolescents</i>
Dental development (and Demirjian)

<i>Subjects in transition</i>
Third molar development (Mincer)
Fusion of speno-occipital/basilar synchondrosis, iliac crest, and vertebral ring
Maturation of hand and wrist (Greulich and Pyle, Tanner–Whitehouse)
Fusion of clavicle sternal end

between 14 and 23 years of age, with complete union at 24 years for both sexes. However, as there are differences between populations, it is recommended to use the proper population standard. The union of the medial clavicle begins at different ages, depending on the population studied. The other indicators are third molar development evaluation according to Mincer classification, and obliteration degree of speno-occipital suture. In the case of fresh and putrefied bodies, which cannot be immediately classed as clear adults or subadults, it is necessary to perform these methods (Table 1).

Adults

Age estimation is more difficult in adults than in subadults because skeletal and dental developments are already complete, creating a consequent increase in the error range. Assessing age in adults must, therefore, be based on physiological degeneration of skeletal and dental structures with age. However, articular degeneration is modified by pathological and occupational factors, which may radically modify the degeneration process, overcoming the importance of aging. The same limits are observed in dental wear, where physiological and pathological elements both contribute to dental structure degeneration with aging. The first step in aging adult remains is choosing one or more methods that will be the most appropriate to the state of body preservation.

Well-preserved remains

This group includes well-preserved bodies that are visually recognizable but remain unclaimed and unidentified. In these cases, apparent age can be estimated by simply examining the corpse; however, this method is unscientific and subjective. A two-step procedure, consisting of combining the pubic symphysis SB system with the dental Lamendin method, can provide a scientific estimation of age. For SB phases I, II, and III, the age estimate is given using chronological interval corresponding to each phase. If the SB phase is 4, 5, or 6, the Lamendin method is applied. In case of lack of pubic symphysis, the fourth rib can be used for age determination of the first four stages, the last four stages being assessed by the Lamendin method. Dental pulp chamber can be used if there are no monoradicular teeth. The Lamendin method is considered the most accurate method of age estimation for decedents over 45 years of age, although it is problematic in subjects over 65 years of age and in cases of periodontal disease. The advantages of this method are that it is very easy to use and

there is minimal impact of population variation on the accuracy of age estimation. If there are no teeth available, in substitution of Lamendin, examiners can use osteon count analysis by the Kerley–Ubelaker and Ahlqvist–Damsten methods. These methods are based on a microscopic analysis of bone section from a long bone diaphysis in order to assess an osteon count evaluation. x-Rays should be performed on these bodies to check for the presence of dental or osseous elements, which may still be in formation or fusion. In a growing number of institutes, CT scans are available and allow the evaluations of areas, such as the pubic symphysis and the auricular surface, that are difficult to reach anatomically in less time; however, applicability still needs to be tested.

Decomposed remains

(a) The second group will be called ‘decomposed bodies,’ which includes putrefied, mummified, and saponified bodies. Slightly burnt bodies will also be added to this category, which entails all states of preservation that severely alter physiognomy.

In these cases, not even apparent age can be given; therefore, biological methods are even more important. The same procedure as discussed elsewhere in this encyclopedia is proposed.

Skeletonized remains

As all parts useful for aging are exposed, the examiner must choose using between one preferred method and many methods with a multifactorial approach. Although the literature is still unclear in relation to this issue, the authors suggest using the two-step procedure described in the well-preserved bodies paragraph above. If teeth are missing or the pubic symphysis and ribs are damaged, then some methods – such as suture closure – should be avoided. The auricular (Meindl–Lovejoy–Mensforth) method may be a better option, even if intraobserver error is significant, leading sometimes to inaccurate results. This method should be used in association with evaluation of the acetabulum, a more recent method that – although it requires more testing – is especially promising for 60-year-old, or older, individuals. In all these cases, if any bone indicator suggests a very young adult, it is advisable to confirm the state of epiphyseal union of the sternal end of the clavicle and of the iliac crest (see section ‘[Transition phase \(between 20 and 30 years\)](#)’).

Calcined remains

In cases of calcined remains, such as those found in burnt cars, the choice of the method depends on the preservation of anatomical sites and how badly they are burnt. x-Rays should always be performed on burnt bodies to check for dental and osseous developments, in case the person is an adolescent or subadult. If the remains consist only of burnt bones, a possible method could be osteon counts as heat may not significantly alter osteon shape or disposition for these purposes. One should, however, use such methods cautiously when the anatomical site of the bone is not determined, when the histological structure can no longer be identified, or when the bones

are too fragmented. None of the dental methods for adults should be used for aging burnt remains apart from, perhaps, pulp chamber methods, which, however, need further testing.

Body parts

Skull with teeth

- If all teeth are present, the authors recommend the use of Lamendin if PMI can reasonably point to a recent case. The Lamendin method has not been tested on historical samples or even samples that have been buried in soil for several decades. Therefore, in these situations, the authors recommend the use of the pulp chamber method, which considers the ratio between pulp chamber and total dental area in upper and lower canines because it has greater possibilities of not being affected by taphonomy and is simpler to run than cementum annulation techniques.
- If no monoradicular tooth is present, the available methods are pulp chamber and amino acid racemization. Although the latter seems to be more precise than all other methods, it should be kept in mind that very few labs in the world perform this difficult technique and have prepared calibration curves for this purpose; that this technique is much more expensive than any other method; and that the method has only been tested on recent material, and never been compared to other methods on the same sample.
- Spalding et al. and Ubelaker et al. have pointed out that radioisotope concentration analysis in dental enamel provides a method of aging. Between 1950 and 1963, the increase in carbon-14 by the thermonuclear device allows one to verify that childhood and consequent teeth development have occurred before that time threshold, with reconstruction of date of birth.

Skull with no teeth

- Little should be assumed when teeth are not present. Loss of teeth may occur at any stage of life and can be caused by social habits, drugs, infections, and diseases. Edentulous mouths do not necessarily belong to an old individual although it is more probable.
- Suture closure methods have extremely large intervals/standard deviations for forensic purposes and are affected by a wide inter- and intraindividual variability in case of maxillary suture and cranial sutures (ecto- and endocranial). Moreover, sutures in the same individual may show different degrees of fusion.
- For osteons, some published methods seem to allow one to place age, depending on the number and the maturity of osteons, into gross ‘young-middle’ and ‘old’ categories. However, no equations exist as for long bones; thus, the accuracy is very poor. Amino acid racemization on bone, on the other hand, is much less accurate than on teeth because of bone remodeling and, therefore, cannot be recommended.

Entire postcranium (no skull)

- The authors recommend using pubic symphysis to age a subject when no skull is available. If the result is within the first three stages of Suchey–Brooks, it should be left at that. If it belongs to the last three stages, a method that is more

accurate and precise for older individuals should be used, such as osteon analysis. The examiner can always confirm age estimation by pubic symphysis by the fourth rib and auricular surface, or can perform an analysis of the acetabulum.

Torso only

- The Iscan method has proven to be reliable, especially in females and in subjects 60 years of age and older. In males, the recent literature has shown a morphological variability between the articular surfaces of different ribs.

Upper limbs

- RX examination and assessment of humeral bone structure in the Acsadi and Nemeskeri combined method.

Lower limbs

- Osteon counts with adequate equations by the Kerley–Ubelaker method.

In conclusion, as regards aging adults, it should be mentioned that there are virtually no methods useful for the estimation of age at death after 60 years of age: it is impossible to discriminate between 70 and 80 or 90. A summary of all the recommended methods, including the literature references, is shown in [Table 2](#).

The Living

Age estimation of the living has become more and more common. The main issues of age estimation in the living concern ‘imputability’ with regard to criminal activities, asylum seekers, illegal immigrants, and unaccompanied minors: the age limit might be 14, 16, 18, or 21 years, depending on the country. Aging the living is also important in issues surrounding adoption and old-age pensions (50, 55, 60, or 65 years of

age, again depending on the country). Aging the living requires the use of noninvasive methods as well as higher levels of accuracy and precision than the dead, due to specific legal requirements. In agreement with the recent work of the Study Group on Forensic Age Diagnostic, the authors believe that a correct assessment of age estimation in the living should consist of three steps: a physical (or clinical) examination, an estimation of bone development, and an estimation of dental development.

Clinical Examination

1. For nonadults or young adults, the first step in age estimation is the collection of medical information through a complete anamnesis. Physiological and pathological factors, as well as social and economic contexts, influence body development and sexual development; this physical examination will verify growth and particularly sexual development. First, height and weight must be accurately measured, and the measurements should be compared with the specific percentiles concerning the standard growth of children provided by WHO and CDC. These percentiles are commonly used in clinical practice. Pediatricians commonly use the Tanner stages, an analysis of sexual traits in males and females. The Tanner method considers breast and pubic hair development in females, while in males, increase in testicular volume and pubic hair is taken into account. Important limits concerning racial and interindividual variability have been pointed out, and Tanner himself has stressed that the method should not be used for chronological age – thus forensic – purposes.
2. For adults, although bodily and sexual growth have terminated, a complete physical examination should not be excluded. In females, menopause (also affected by ethnic and interindividual variability) in addition to physical modifications can be confirmed by hormonal dosage.

Dental Assessment

Adults

Age assessment is more difficult in living adults than in living subadults; at present, there is no recommendation concerning the most appropriate method to use. Root methods may provide a useful tool for age estimation in adults if future literature will offer further population data confirming their reliability. The aforementioned amino acid racemization in dentine has also been suggested; however, this method involves destruction or damage of the individual’s tooth. Very recently, DNA alterations linked with aging – such as age-dependent accumulation of the 4977 bp deletion of mitochondrial DNA and the attrition of telomeres – have shown promise. These are currently very preliminary results, however, and must be confirmed and standardized.

Children and young adults

Among the numerous dental methods, Demirjian and Mincer (for the third molar) are the most commonly suggested by the literature; Demirjian is based on the growth assessment of several teeth (usually half a dental arch). It is considered a reliable method that is easy to use and offers well-defined

Table 2 Recommendations concerning age estimation methods in case of well-preserved, decomposed, skeletonized, and calcined remains; standard errors are between 7 and 15 years

Methods	Remarks
Well-preserved and decomposed	
Suchey–Brooks	More reliable between 20 and 40 years
Iscan	Higher reliability after 60 years
Lamendin (in TSP protocol)	Periodontal disease influence; high reliability between 40 and 60 years
Microscopic analysis of osteons	More time consuming
Skeletonized	
Suchey–Brooks	
Iscan	
Lamendin (in TSP protocol)	
Auricular surface	Interindividual and intraindividual variations
Calcined remains	
Microscopic analysis of osteons	With great caution

morphological stages. Several studies have shown the high dependence on the specific characteristics of the population. Moreover, where the original method was applied with specific calibration curves, the results showed an increase in accuracy. This confirms that the high ethnic variability requires particular caution in the discussion of the final result. The Mincer et al. method also is a good option for using the third molar to age older adolescents. This method has been tested on various populations with a high variability in age threshold: every Mincer stage has been verified with different mean ages. A recent study showed that the best methods as regards bias (average difference) and median absolute difference between the estimated and chronological ages were Willems's (with a bias of 0.12 years and a difference of 0.52 years) and Liversidge's flat distribution (with a bias of 0.03 years and a difference of 0.69 years) in a sample of 946 children. Although the literature suggests the use of classical methods, other methods should not be disregarded. Pathological factors have not been considered so far, but they should be among the exclusion criteria of subjects from the studies, and the dental age estimation methods should be applied to subjects who have a healthy dental profile.

Skeletal Assessment

1. For adults, see the section titled 'Dental Assessment.'
2. When the legal age limit is around 18 years, the method of choice for aging subadults is an x-ray on the hand-wrist area (generally the left hand, but when the person is left-handed, the right hand may be preferable) to evaluate the degree of fusion of the cartilage in this area. The most popular is the GPA, which provides a series of x-ray standards for the hand and wrist from birth to 17/18 years of age for females and 19 years of age for males. This method is comparative and consists of the evaluation of the x-ray examination from the proband and the standards from the atlas. The final result includes mean age estimation and an error range. The TW method is based on a scoring system that evaluates the ossification degree and morphological appearance of the ossification nuclei and bones in the hand and wrist. A maturity score is then given, with the indication of mean age and error range. There is a majority consensus that both methods reliably assess age, though GPA is quicker and more user-friendly. The FELS computerized method provides an evaluation concerning concordance between the wrist and hand x-ray pattern and the age declared. It is, however, more complex and less user-friendly than the other two methods.

Ethnic, pathological, and socioeconomic statuses affect skeletal development; therefore, the issue of the applicability of methods to different populations has been questioned. A study of GPA on 1390 males and females ranging from 1 day to 18 years of age showed that the bone age was overestimated in Asian and Hispanic children, who seemed to mature sooner than their African-American and white peers. Thus, population data are extremely important and are beginning to appear for the GPA and TW methods. As shown in a recent meta-analysis, however, age estimation in living individuals cannot be considered accurate when only x-ray methods on the left

hand and wrist area are used; exhaustive combinations of various procedures (i.e., physical examination, dental, and skeletal methods) must also be used.

3. In countries where the age of 21 years may be of some legal interest, the fusion degree of the clavicle sternal end may provide relevant information because it occurs in the useful age range for imputability assessment. Use of NMR, although the first results have yet to be confirmed, may overcome the limitations of the use of x-ray examination.
4. Use of x-rays on the living can endanger health. Established doses for x-ray examinations in forensic age estimations are low and vary from less than 0.1 mSv (left-hand x-ray) to up to more than 800 mSv (CT), and despite the higher sensibility of children to radiation, hand radiographs are harmless. Computed tomography on children is, however, a relatively high-dose procedure. Ultrasonography and NMR technology may provide a healthy alternative to x-rays. Ultrasonography has been mainly aimed at the assessment of ossification of clavicular sternal extremity and an ultrasonographic version of the GPA was developed. At the moment, however, the use of the ultrasonography and NMR technique for forensic purposes needs adequate standardization (Table 3).

Age Estimation in Juvenile Pornography Images

The crime of pedopornography is based on the specific ages that each country considers relevant for this crime (usually 14, 16, or 18 years, depending on the country). In these cases, judges require age estimation of possible victims who may not be physically present, requiring examiners to create age estimates based only on two-dimensional (2D) images in

Table 3 Recommendations concerning age estimation methods in the living

Methods	Remarks
Subadults	
Physical assessment and Tanner sexual classification	High racial and interindividual variability; strong criticism concerning its use for forensic purposes
<i>Bone development (radiological)</i>	
Greulich and Pyle atlas and Tanner-Whitehouse	Greulich and Pyle user-friendly, quick; some population data available
Clavicle sternal end fusion (radiological)	Still being tested
<i>Dental development (radiological)</i>	
Demirjian method	Some population data available
Mincer method	Asset: gives probability of having reached 18 years; disadvantage: high frequency of third molar agenesis (up to 8% in Caucasoids)
Adults	
Physical assessment and hormonal dosage for women	High racial and interindividual variability
Pulp chamber-based methods	High error range; need for further experimental data

photos or videos, which may be of poor quality. The sexual characteristics of possible victims, as seen in pictures or videos, are often deceiving; a new approach for age estimation from 2D pictures is needed. A research field, which may hold some answers, could be the morphological and metrical analysis of the face, which may have a relationship with chronological age. In the videos in which possible victims smile or open their mouths, it may be possible to evaluate dental eruption and development in order to provide a rough age range estimate. Thus, in general, physical and sexual maturation stages should be used with great caution for forensic purposes, particularly in regard to photographic material.

In Court

Judges are often required to make decisions based on whether or not an individual has reached a specific age threshold, and therefore, they may require precise and definite age evaluations in which explanation of error is crucial. Most methods give standard errors or standard deviations, allowing examiners to provide a judge with an age range; for example, 17.5–18.5 years. Giving the probability of that person actually having reached the threshold (e.g., 18 years) might also be helpful to the judge. In this perspective, methods such as the Mincer's, which, along with the mean age and error, give the probability of the subject having reached the limit of 18 years, could be more useful to the judge.

In a study performed on 47 judicial immigration cases, skeletal and dental methods provided borderline results that – by making it difficult to determine whether the defendant was an adult or a juvenile – would have severely complicated the sentencing portion of the proceedings. An examination of the final sentences showed that when the Mincer method was applied, therefore allowing the judges to know the probability of the individual having reached the age of 18, the judges were appreciative. Knowing the age of the defendant with some degree of confidence allowed the judges to better carry out sentencing: when the probability of the individual of being 18 or over was over 70%, the judges felt 'confident' in taking the risk of sentencing the individual as an adult.

Conclusions

This article makes the case that despite the enormous literature on this issue – perhaps one of the most common topics in anthropological publications – age estimation for the dead or the living, and particularly for adults, can provide only large age ranges. Although new methods may be tempting, for forensic purposes, it is safer to use traditional, standardized, and tested methods. When using a combination of methods, the simple pooling of data cannot be performed because every method expresses its error range in different ways (mean error, standard deviation, etc.) and some do not even provide an error indication. Interpolating results from different methods, however, is possible provided a rough age indication is given. This can be performed by principal component analysis, which has proven to be reliable. The consequent issue concerns how to present results to investigating authorities: an age estimation report must include indications about

the methods performed, information about specific limits, and the mode of processing data. Finally, it is necessary to point out that age estimation concerns biology, where variability is the rule; even considering population data, every individual may show different aging patterns. Correct age estimation must consider this unavoidable limit, in order to define the precision and accuracy of the results provided. At the moment, the most challenging field of aging is for the population above 65 years of age as no method, so far, has been found suitable for this purpose. When considering that this population is the fastest growing in most parts of the world, it must be considered a major concern. More research is thus needed and here as well, similar to other fields of forensic sciences, the future might be in DNA studies.

Stature and Build

K Krishan, Panjab University, Chandigarh, India

T Kanchan, Kasturba Medical College (affiliated to Manipal University), Mangalore, Karnataka, India

© 2013 Elsevier Ltd. All rights reserved.

Introduction

Stature and body build are quantitative measures of physique that are indicative of individuals' physical growth and development, and reflect the health, nutrition, and genetics of a population. Stature is the linear dimension of the skull, vertebral column, pelvis, and bones of the lower limbs. Estimation of stature is fundamental to the evaluation of skeletal remains, and is therefore an important aspect of forensic identification. Stature – along with age, sex, and ethnicity – is one of the 'Big Four' identifying factors in forensic anthropology. This baseline biological information, known as the biological profile, helps forensic scientists identify victims by narrowing down the pool of possible victim matches. Age, sex, and ethnicity should be taken into account when estimating stature in forensic examinations. Stature estimation is a major domain of medicolegal investigation in establishing the biological profile of unknown, fragmentary, and mutilated remains. Body build is a measure of overall body size of an individual, and includes both stature and body mass.

Individuals' stature is influenced by genetic and environmental factors such as health, disease, nutrition, and physical activity. Physical activity, in addition to good health and proper nutrition, encourages bone growth and development. The extent of physical activity during the growth period determines whether an individuals' genetic potential for stature is achieved.

The body proportions of different ethnic groups may also vary because of selective adaptation to different climate zones characteristic of each endogamous group. It is therefore desirable to derive stature estimation formulae for different ethnic groups. This is difficult, however, because of the practical difficulties in deriving these formulae for each ethnic and caste group, particularly in countries such as India and many African countries, where hundreds of such groups exist. Because of this, researchers' opinions on the need to derive regression models for each ethnic group are divided. The issue, however, is simplified in regions inhabited by homogeneous population groups where a single regression formula represents the region.

Measures of Body Build and Body Size

Estimation of body build and body size has received much less attention than stature estimation in forensic anthropology, but is nonetheless important in the evaluation of skeletal remains. Among scientists, it is generally agreed that the postcranial features have a more direct relationship to overall body size than cranial dimensions, and can therefore produce the most accurate estimates of body mass. Two methods can be used to estimate body mass from postcranial skeletal remains: mechanical method and morphometric method. Mechanical

method relies on the functional association between weight-bearing skeletal elements and body mass. Mechanical methods may employ articular surface dimensions or use diaphyseal breadths and cross-sectional dimensions of the bones for the estimation of body mass. Articular surface dimensions are less influenced by the differences in the activity level or muscular loadings during life than diaphyseal dimensions. Morphometric methods of estimating body mass reconstruct body size and/or shape from the available bones. Morphometric methods for reconstructing body mass based on stature estimation alone have been developed by researchers. On the basis of a worldwide sampling of modern humans of diverse body shape, Ruff derived a morphometric method – which is a combination of stature and body breadth (bi-iliac or maximum pelvic breadth) – that provides relatively accurate estimates of body mass. According to Ruff, articular surface dimensions are less influenced by differences in activity levels and muscular loadings during life when compared to diaphyseal dimensions and thus are more important. In addition, attempts have also been made to estimate body mass from metatarsal dimensions, pelvic bi-iliac breadth, long bone lengths, and femoral head diameter.

Methods of Stature Estimation

The two basic methods of stature estimation in forensic examinations are the anatomical method and the mathematical method. The anatomical method of stature estimation was introduced by Fully. Fully's method estimates individuals' stature by summing the measurements of all the skeletal elements that contribute to the stature and adding a correction factor for the soft tissues. The skeletal elements essential for the estimation of stature are skull, vertebrae, femur, tibia, talus, and calcaneus. Lundy later devised a correction index to account for the thickness of the scalp, intervertebral disks, and soft tissue of the sole.

A revision of Fully's method by Raxter and colleagues is considered the best and the most accurate method of stature estimation in spite of its drawbacks: it is intricate, laborious, time consuming, and requires the essential components of the skeleton to be present. Fully's original method does not provide explicit directions for taking all of the necessary measurements. Raxter and colleagues revised Fully's anatomical method for reconstruction of stature by testing, then clarifying, the measurement procedures. Raxter et al. tested Fully's process on 119 adult black and white male and female cadavers of known stature from the Terry Collection. The cadaveric statures were adjusted to living statures, according to the recommendations of Trotter and Gleser. Raxter and colleagues found that statures derived using the Fully's original technique underestimated the living stature by an average of about 2.4 cm and that the correction factors applied by Fully to convert summed

skeletal height to living stature was too small. Fully's technique did not take into consideration the size of cartilage and other soft tissues that might affect proper spacing. Hence, Raxter and colleagues derived new formulae to calculate living stature from skeletal height.

The mathematical method of stature estimation is based on the standard of deriving a formula that can be applied directly to estimate stature from a given bone or body part in forensic examinations. Estimation of stature using mathematical formulae is based on the principle of a definite biological relationship that exists between stature and the body parts, especially those which contribute directly to individuals' stature such as the head, trunk, vertebral column, pelvis, lower extremity, and feet. The well-defined relationship between these parts allows a forensic scientist to estimate stature from various bones and body parts. The mathematical method of stature estimation includes two submethods: the multiplication method and the regression analysis method. Many earlier studies have utilized either or both of these methods of stature estimation; however, studies have shown that the regression method of stature estimation is more accurate and reliable than the multiplication factor method. The studies on the extent of variability in estimated and actual stature using both these submethods, however, are limited in literature.

Anatomical method is considered advantageous over the mathematical method of stature estimation as the former gives more reliable stature estimates. However, all bones required for stature estimation using Fully's method may not be available in routine forensic practice, thus limiting its utility. Therefore, the mathematical method remains a more popularly used method of stature estimation in forensic and medicolegal investigations.

Stature Estimation from Long Bones

Regression analysis is based on the linear relationship between dimensions of bones, body parts, and stature. Various regression formulae have been derived for estimation of stature from long bones in different population groups worldwide (Table 1). Trotter and Gleser conducted a major on stature estimation using humerus, radius, ulna, femur, tibia, and fibula bones from black and white Americans. Samples were taken from the Terry collection and from remains of World

War II American military personnel. Trotter and Gleser used these measurements to formulate sex- and population-specific regression equations. Later, they revised these formulae using a large number of skeletons of black and white American service members who were killed between 1950 and 1953 while serving in the Korean War. They also devised regression formulae for Americans of Mexican, Puerto Rican, and Asian origin. Following these major studies on stature estimation, a variety of authors worked in different regions of the world to generate standards for stature estimation. Additional regression formulae were developed by Allbrook, for British and East Africans, in 1961; by Olivier, for French men and women, in 1963; by Yungchao and colleagues, for Chinese, in 1979; and by Černý and Komenda, for the Czechs, in 1982. Dupertuis and Hadden later provided bone/stature ratios and regression formulae for Americans from femur, tibia, humerus, and radius measurements using materials from the Hamann-Todd Collection. They also recommended that a combination of two or more bones be used to provide better estimations of stature.

Jantz modified the Trotter and Gleser formulae in view of the secular trends in modern population. Jantz tested the Trotter and Gleser formulae for femur and tibia using the data from the Forensic Data Bank at the University of Tennessee, and observed that stature estimates differed from one another by about 3 cm. Jantz and his colleagues observed that Trotter and Gleser's study inappropriately measured tibia length, resulting in tibia measurements that were 10–12 mm shorter than the actual measurements. These faulty measurements were responsible for the overestimation of stature (averaging 2.5–3.0 cm) when the regression formulae were used on the appropriately measured tibia.

Ross and Konigsberg provided stature estimation formulae for Balkans by measuring long bones from a sample of 177 Eastern European males, including Bosnian and Croatian victims of war. They compared the estimated stature from the East European sample with a reference sample of 545 white American males – Trotter and Gleser's data from World War II – and observed that Trotter and Gleser's formulae systematically underestimated the stature of Balkans. Ross and Konigsberg concluded that the stature prediction formulae developed for white Americans may be inappropriate for European population because Eastern Europeans are typically taller than white Americans.

Table 1 Regression models derived for stature (cm) estimation from various bones in different populations

Population/origin	Males	Females
Caucasoids (cm) (Trotter and Gleser)	$2.38 \times \text{Femur length} + 61.41 \pm 3.27$	$2.47 \times \text{Femur length} + 54.10 \pm 3.72$
Negroids (cm) (Trotter and Gleser)	$2.11 \times \text{Femur length} + 70.35 \pm 3.94$	$2.28 \times \text{Femur length} + 59.76 \pm 3.41$
Mongoloids (cm) (Trotter and Gleser)	$2.15 \times \text{Femur length} + 72.57 \pm 3.80$	–
Chileans (cm) (Ross and Manneschi)	$2.53 \times \text{Humerus length} + 820.36 \pm 36.7$	$1.91 \times \text{Humerus length} + 989.28 \pm 41.5$
Chileans (cm) (Ross and Manneschi)	$2.26 \times \text{Tibia length} + 356.48 \pm 31.0$	$1.41 \times \text{Tibia length} + 1026.97 \pm 41.1$
South Indians (cm) (Nagesh and Pradeep Kumar)	$1.882 \times \text{Vertebral length} + 60.699 \pm 4.38$	$1.899 \times \text{Vertebral length} + 55.361 \pm 4.16$
Portuguese population (mm) (Cordeiro and coworkers)	$11.678 \times \text{First metatarsal} + 963.949 \pm 57.0$	$12.006 \times \text{First metatarsal} + 919.146 \pm 43.5$
South Africans Whites (cm) (Bidmos)	$0.87 \times \text{Calcaneus length} + 84.65 \pm 4.56$	$1.25 \times \text{Calcaneus length} + 52.51 \pm 4.59$
South Africans Blacks (cm) (Bidmos and Asala)	$0.63 \times \text{Calcaneus length} + 100.87 \pm 5.34$	$0.82 \times \text{Calcaneus length} + 82.49 \pm 4.98$
Portuguese population (cm) (De Mendonca)	$0.3269 \times \text{Humerus length} + 59.41 \pm 8.44$	$0.2663 \times \text{Humerus length} + 47.18 \pm 6.90$
Portuguese population (cm) (De Mendonca)	$0.3065 \times \text{Femur length} + 64.26 \pm 7.70$	$10.2428 \times \text{Femur length} + 55.63 \pm 5.92$
Thai population (cm) (Mahakkanukrauh and coworkers)	$2.722 \times \text{Femur length} + 45.534 \pm 5.06$	$2.778 \times \text{Femur length} + 40.602 \pm 5.21$
Thai population (cm) (Mahakkanukrauh and coworkers)	$3.015 \times \text{Tibia length} + 52.964 \pm 5.15$	$2.620 \times \text{Tibia length} + 63.089 \pm 5.94$

Auerbach and Ruff calculated regression formulae for indigenous North Americans using femur and tibia lengths. They used 967 skeletons from 75 archeological sites and estimated stature using revised Fully anatomical technique. After comparing the new stature estimation equations with previously available equations using several archeological test samples, they observed that the new stature estimation equations were more precise than those previously available, and recommended the use of derived formulae throughout most of the North America.

Stature Estimation from Percutaneous Bone Measurements and Body Parts

The identification of mutilated and isolated body remains has remained a challenging task for forensic scientists. Body parts such as the head, trunk, upper and lower limbs, and feet and hands display a definite biological relationship with an individuals' stature. While forensic anthropologists typically estimate stature from length of the bones, they also examine human remains at mass fatality sites where analysis of the fleshed bodies or body parts is more common. For stature estimation at mass disaster sites where only parts of bodies or mutilated remains are found, the presence of soft tissue on the human remains would usually necessitate dissection to expose skeletal elements to derive metric data for stature estimation; however, it is possible to estimate stature from various parts of the body using anthropometric techniques. In such a scenario, standard anthropometric soft tissue or percutaneous measurements can be used instead of skeletal measurements. Stature estimates derived from anthropometric data are reasonably accurate and eliminate the necessity for dissection when working with fleshed body portions.

Adams and Herrmann compared the results of skeletal measurements and the anthropometric measurements from two studies (National Health and Nutrition Examination Survey and U.S. Army Anthropometric Survey) and found that the U.S. Army Anthropometric Survey models were similar to the skeletal models. The National Health and Nutrition Examination Survey models, however, exhibited weaker correlation coefficients and higher standard errors for the same.

Researchers have successfully estimated stature from measurements on percutaneous bones of living individuals as well as cadavers in different populations worldwide. This has allowed the development of regression formulae for estimation of stature from head, face, and upper extremity measurements in North Indian ethnic groups and the Turkish population; from hand dimensions in the Punjabi Indian, North Indian, South Indian, Mauritian, and Egyptian populations; and from lower extremity dimensions (including foot dimensions) in American, Turkish, North Indian, Mauritian, and Nigerian populations, as well as the Rajbanshis of North Bengal in India.

Stature Estimation from Radiographically Determined Long Bone Length

Scientists have shown that radiographically determined bone lengths can provide stature estimates using regression formulae. While conducting the X-ray examination, however, the

specific position of the subject must be taken into consideration. Size standards of the positives are obtained and landmarks are located on the positives and precise measurements are taken. Researchers have made use of various radiographic methods, such as dual-energy X-ray absorptiometry, computed radiography, and digital radiography, for this purpose.

- Munoz and colleagues estimated stature from radiographically determined lengths of the long bones in a Spanish population. They reported femur and tibia as the most accurate predictors of stature in the population.
- Patil and Mody devised regression formulae for estimation of stature from various measurements of lateral cephalograms in a central Indian population.
- Sarajlic and coworkers measured long bones from the X-rays obtained from the cadavers in a Bosnian population and derived regression formulae for stature estimation.
- Sagir successfully estimated stature from various measurements on radiographs of metacarpals in a Turkish population.
- Petroveckí and colleagues calculated relationship of stature with all the six long bone lengths measured from the radiographs of the cadavers in a Croatian population. Petroveckí and colleagues concluded that the best prediction of stature can be made from the humerus in females and the tibia in males.
- Fan and colleagues measured fibulae and tibiae of living Han subjects of China using computed radiographs and successfully derived regression formulae to estimate stature.
- Hasegawa and colleagues took measurements on radiographically determined lengths of femur, tibia, and humerus in living Japanese subjects and calculated multiple regression models for estimation of stature.
- Kieffer demonstrated the feasibility of creating bone lengths and stature databases of significant size for modern living human population from digital radiographic archives and medical records. He measured the lengths of tibia and fibula from the digital radiograph images and stature measurements were obtained from medical records. Kieffer observed that the bone lengths obtained from radiographic images were almost 3 cm longer than those obtained from skeletal collections; consequently, the stature estimation formulae produce ranges up to 10 cm lower than the currently available formulae. Kieffer suggested that accuracy of stature estimation can be improved by making corrections for the small magnification produced by digital images.

Thus, estimating stature from the radiographic measurement of the length of the long bones of the upper and lower extremity seems to be a simple and practical approach to estimate stature in forensic practice.

Stature Estimation from Small Bones and Other Bones of the Body

Although stature estimation from long bones is more reliable and accurate than from any other bone or part of the body, in some cases, other bones need to be used for stature estimation.

A fair amount of accuracy has been achieved by researchers using foot bones such as calcaneum, talus, and metatarsal bones for stature estimation in various populations. Metacarpals have also been used effectively in stature estimation and regression equations have been derived. Similarly, the vertebral column and its parts, pelvic dimensions, scapular measurements, sternal measurements, and clavicle dimensions have been utilized for stature estimation in some population groups. Stature estimation from these bones is quite valuable when the long bones are not available for examination.

Estimation of Stature from Fragments of Bones

In a number of forensic and archeological cases, only bone fragments or parts of long bones are available for examination. In such cases, stature estimation from parts of the bone can help in identification of the victim. Studies have shown that stature can be estimated from fragmentary bones by either a direct method or an indirect method. Direct method involves estimation of stature directly from the individual measurements or combination of measurements of fragments of the bone. The indirect method involves the calculation of maximum length of the bone from the measurements of its fragments that is followed by stature estimation from the estimated maximum length of the long bone. Indirect method is considered more useful and accurate than the direct method of stature estimation from fragmentary bones. However, Bidmos has observed that the direct method of stature estimation is more accurate and reliable than the indirect method and is less complicated when the direct measurements are involved in stature estimation.

Most of the studies on stature estimation from fragmentary remains have been conducted on femur fragments from various population groups. Chiba and Bidmos derived regression equations from fragments of tibia that allow estimation of full-length tibia measurements and stature. These studies show that in the absence of intact long bones, the equations derived from the fragments of the bones can provide a reliable estimate of skeletal height and living stature.

Secular Change and Variation in Limb Proportions in Relation to Stature in Different Populations

Secular change is the increase or decrease in size over a period of time in a population, and allometry is the proportional relationship of anatomical structures in humans and other biological organisms. Studies on secular change and allometry have observed differential limb proportionality between sexes and among populations, which could affect the accuracy of stature equations depending on the skeletal elements used to calculate such estimates. In other words, the long bone lengths and body proportions of one population do not necessarily correlate with the stature in another population. This may be attributed to the genetics and environmental factors – such as nutrition and disease – of a population, which result in variations in body and limb proportions among population groups. The environmental conditions appear to be the primary controlling factors in an individual achieving the fixed genetic

potential for stature. These factors account for the necessity of population-specific regression formulae, which were discussed previously.

Allometric secular changes in black and white Americans has shown that stature formulae based on dated measurements – such as Trotter and Gleser's nineteenth-century samples from the Terry collection – are inappropriate for use in modern forensic cases. It is, therefore, recommended that the regression equations should be derived at opportune intervals to take account of secular trends in a population.

Factors Affecting Stature Estimation in Forensic Examinations and Making Population Standards and Databases

Factors such as aging, limb asymmetry, diurnal variations, gender, and measurement error can also affect the stature estimation of victims. The effect of aging on stature estimation is well known. Stature alters as an individual goes through the life cycle, increasing during youthful growth and development, leveling off for several decades after maturity, and decreasing in later adulthood. The effective loss of stature begins at about 40 years of age and continues rapidly thereafter. Thus, it is recommended that age group categorization of the subjects should be done for making stature estimation standards and databases in a population.

Another factor that can affect stature estimation is the presence of limb asymmetry in individuals and a population as a whole. Limb asymmetry is considered as a general and natural phenomenon in the human body. Bilateral asymmetry in the human body exists because of genetic as well as environmental causes and is a good indicator of developmental stability in an organism. Thus, different formulae needs to be derived for estimation of stature from the right and left sides. While examining human remains, forensic anthropologists should take asymmetry into consideration and apply an appropriate formula for estimation of stature for that side of the body.

Stature is subject to diurnal variations, and the time of the day when an individual's stature is measured can affect the measurements. Individuals have maximum stature shortly after waking (whether from nighttime sleep or an afternoon nap), and are shorter later in the day due to the gradual compression of the intervertebral disks that occurs during walking, standing, and sitting. Taller and heavier individuals have a greater potential for diurnal variations than lighter or smaller persons. Significant diurnal variation is known to affect the stature database in forensic examinations. It is, therefore, recommended that individuals' height be measured at a defined time in a day to avoid variations in stature that may affect the generated standards and formulae derived for estimation of stature.

Technical or personal errors inherent in measuring stature of individuals or measuring bones can substantially affect stature estimation and, therefore, must be considered in forensic casework. Anthropometric measurements are taken using standardized instruments and techniques. Height measurements are typically taken with an anthropometer or a stadiometer; osteometric boards, Flower's calipers, and sliding calipers are used to take measurements of long bones and skeletal material.

These measurement techniques must include calculations of measurement error in terms of inter- and intraobserver bias. A minimal error can affect the reliability and precision of analysis, leading to erroneous conclusions. The precision, reliability, and reproducibility of the measurements are essential. Individuals' posture (such as a slouch, which may occur because of aging or ill health) or the effects of footwear may also substantially alter stature measurements.

Gender also has an effect on stature estimation. It is customary to derive regression formulae separately for males and females because of statistically significant differences in stature and dimensions of male and female bodies. Estimation of sex thus becomes a critical requirement in applicability of sex-specific regression models in stature estimation. It may not always be possible to estimate sex with reasonable accuracy, and hence, there is a need to derive universal regression formulae for estimation of stature that can be applied in remains with unknown sex.

Glossary

Fisher's linear discriminant Developed by R. A. Fisher, the linear discriminant finds a set of weights, or coefficients corresponding to each variable, which maximize the differences between groups. This means that variables exhibiting greater differences between groups receive more weight than those with smaller differences. The linear discriminant maximizes the correct classification of individuals.

Geometric morphometry Evaluation of morphology using Cartesian coordinates, which may be two or three dimensional. It provides more information

about where differences occur than ordinary morphometry.

Mahalanobis Generalized distance. A statistic developed by P. C. Mahalanobis which produces a multivariate assessment of the difference between two population samples, expressed as a single number. It takes into account variation and covariation. It is a summed distance, so in general, more measurements mean larger distances.

Morphometric Evaluation of morphology by measurement.

Morphoscopic Evaluation of morphology by observation. It usually means scoring the traits as present or absent, or ranking them, in contrast to measuring them.

Introduction

Ancestry is one of the components that go into the biological profile. The biological profile is a description of a person estimated from the skeleton, including, along with ancestry, sex, height, and age. The biological profile is the initial stage in identifying unidentified skeletal remains, and ancestry is arguably the most difficult. Sex, height, and age are relatively fixed attributes and not subject to interpretation. Not so with ancestry. Ancestry pertains to the individuals in one's genealogy, but in forensic anthropology, it has the further implication of identifying the region of the world from which those ancestors originally came. The rise of hybrid groups in the past few hundred years, for example, many Latin American populations and African Americans, has resulted in many whose ancestors came from widely different parts of the world. To make matters more difficult, ancestry is connected to the highly controversial concept of race, and has come into use largely to avoid that term, often regarded as emotionally charged. Regardless of what it is called, forensic anthropologists have been criticized for using the terms, and for including them in their biological profiles. The basis of the criticism is that ancestry is a social construct with little or no biological meaning, and therefore forensic anthropologists are unable to reliably estimate it and risk providing faulty information to law enforcement. Tests designed to demonstrate that ancestry estimation is unreliable are often not grounded in modern concepts of human variation and are set up with unrealistic expectations, ensuring that they will fail, thereby supporting the preordained conclusions that race/ancestry is a flawed concept and that attempts to assign individuals to ancestry groups cannot be successful. Critics also argue that use of a priori-defined groups biases results, but recent work in statistical modeling has shown that human crania sort themselves into geographic groups without prior definition.

Forensic anthropology is rapidly incorporating what we know about human variation and population structure into its ancestry assessments, and is also contributing new knowledge to those disciplines. It is also important to understand

growth and secular changes for making ancestry assessments. Secular changes in skeletal morphology have been documented in many groups in different parts of the world, which necessitates the use of appropriate modern reference samples. Availability of such samples is one of the most critical needs to put ancestry estimation on a sound footing.

Resources

Criteria for ancestry estimation, like those for sex, height, and age, require documented skeletons from which to derive them. In the early days of forensic anthropology, this purpose was served by anatomical collections, such as the Terry and Todd Collections from St Louis and Cleveland, respectively. These collections contain skeletons belonging to people primarily born in the latter half of the nineteenth century. These collections may still serve useful purposes, but for ancestry estimation, the large changes in the skeleton and particularly the cranium have made them inappropriate. The problem has been addressed in two ways. (1) Development of a database of modern skeletal measurements obtained from forensic cases. This database is known as the forensic anthropology database and is maintained at the University of Tennessee, Knoxville. Measurements are taken while the skeleton is in a forensic laboratory, and information about the person becomes available when a positive identification is made. Ancestry, along with sex, height, weight, and any other information, is then attached to the record. Ancestry is obtained from records such as missing persons' reports, police, or medical records. As such, it is essentially self-reported. (2) Development of modern collections of donated bodies, specifically donated for that purpose. The University of Tennessee's William M. Bass collection is the largest such collection, numbering around 1000 skeletons at the time of this writing. The donated collection at the University of New Mexico also contains significant numbers of skeletons. The University of Tennessee's program relies heavily on predonors, that is, individuals who make

arrangements to donate their bodies prior to death. This in turn provides the opportunity to obtain information, including self-reported ancestry, from them.

The Bass-donated collection contains mainly Whites, some Blacks, and a few Hispanics, Asians, and other ethnicities. The database of cranial measurements collected by W. W. Howells contains world samples, but nearly all are composed of individuals born in the nineteenth century or earlier, some several thousand years old. Nevertheless, it is often useful in assessing the part of the world from which an unknown cranium may originate.

There are hundreds of skeletal collections held in institutions around the world, although their suitability to serve as training samples for forensic identification criteria, ancestry in particular, varies considerably. They are too numerous to mention specifically, although two in South Africa are particularly noteworthy: the Raymond Dart Collection and the Pretoria Bone Collection. The Dart Collection in Witwatersrand, apparently inspired by the R. J. Terry collection, contains remains of individuals of both African and European ancestry, mostly with nineteenth-century birth years. The Pretoria bone collection has the added advantage of containing remains of individuals mainly born in the twentieth century. Both individuals of African and European ancestry are represented. The Pretoria collection has considerable potential in understanding skeletal variation in recent South Africans, and in developing ancestry criteria for that country.

Why Do Ancestry Estimation?

Ancestry estimation is most commonly conducted in medico-legal situations as part of the biological profile, as the first step in identifying unknown skeletal remains. Ancestry is normally included on missing persons' reports so the ancestry estimate provided by the forensic report helps narrow the field of candidates. There are other contexts in which ancestry estimation can be important. The passage of the Native American Graves Protection and Repatriation Act in 1990 and the National Museum of the American Indian Act allows the return of Native American remains to their lineal descendants, provided cultural affiliation can be established. Ancestry estimation is often a component of establishing cultural affiliation. This normally involves comparing the remains in question to documented series representing tribal claimants. Questions may also arise because museum records are not always accurate. Sometimes remains said to be Native American are actually White or Black. Internationally, repatriation has also become an issue. Indigenous Australians have been the most successful in obtaining remains from institutions in Europe and America. As is the case of Native Americans, it is often necessary to confirm by ancestry estimation that remains are actually of Australian origin.

Estimation from the Cranium

Historical

Cranial morphology has long been the choice for estimating ancestry. The historical development of ancestry estimation can be conveniently divided into three stages.

The first stage involves assessing ancestry visually using traits, often referred to as morphoscopic traits. This approach dominated the first half of the twentieth century, but continues to the present in a modified form. It is derived from attempts to organize the world's human populations into racial types based on suites of features each race was said to have. The most influential figure in establishing these lists was E.A. Hooton of Harvard University. Although Hooton's trait list was never published and he did not use it to specifically estimate ancestry, it had a major impact on traits used by forensic anthropologists through his students and their students who were the early forensic practitioners. These traits continue to be included in introductory texts in forensic anthropology. An example of commonly used traits and their association with racial groups is shown in Table 1.

Effective use of visual assessment is experience based. Forensic anthropologists who have broad experience in crania from diverse populations can often do well in estimating ancestry through visual appraisal. The problem is that this experience cannot readily be communicated to students and it is difficult to know error rates. The second stage in ancestry estimation attempted to deal with these problems through measurement and statistical analysis. This stage required the appropriate statistical techniques and computer data-processing capability to handle the laborious computations. The statistical techniques rely mainly on Mahalanobis generalized distances and linear discriminant analysis, both of which were developed early in the twentieth century, but were little used because of the heavy computational burden. These techniques were introduced into forensic anthropology for sex and ancestry in the late 1950s and early 1960s. They are some of the earliest uses of computer technology in anthropology.

The well-known Giles and Elliot discriminant functions allowed a skull to be classified as Black, White, or American Indian. The reference or training samples were the Terry and Todd collections for Blacks and Whites, and Indian Knoll, an Archaic site, for American Indians. The Giles and Elliot discriminant functions were widely used by forensic anthropologists for 30 years. Giles and Elliot and other early functions provided the discriminant coefficients, or weights, which were multiplied by the measurements and summed, to obtain a discriminant score, which could then be compared to a sectioning point to obtain the classification. Giles and Elliot also provided a graph on which the unknown skull could be

Table 1 Example of traits traditionally used by forensic anthropologists to assess ancestry

<i>Trait</i>	<i>White</i>	<i>Black</i>	<i>Native American</i>
Inferior nasal border	Sharp	Guttered, no sill	Indistinct
Palate shape	Triangular	Rectangular	Parabolic
Nasal bones	Tower	Quonset hut	Tented
Cranial sutures	Simple	Simple	Complex
Nasal aperture	Narrow	Wide	Medium, rounded
Postbregmatic depression	Absent	Present	Absent
Orbit shape	Sloping	Square	Rounded

plotted to obtain a visual picture of its relationship to the reference samples and which could also be included in the forensic report.

These early functions required that all the measurements be present in order to use them. This presents a serious liability because fragmentary crania are not uncommon in forensic work, often making complete measurement sets impossible.

The third stage in ancestry estimation depended on the confluence of personal computers and the availability of more appropriate databases. This has allowed relatively easy computation of discriminant functions and many have been published. Most importantly, new databases and more powerful personal computers allowed the development of software with the flexibility to allow users to choose groups and variables based on the needs of a particular case or set of remains. This development occurred with the release of Fordisc, which presents the user with a wide range of variable and training sample choices, classifying the unknown specimen anew each time.

Current Status

Forensic anthropologists are dealing with forensic cases drawn from increasingly complex populations, making ancestry the most difficult component of the biological profile to estimate. In the United States in particular, the influx of immigrants from Latin America, especially Mexico, has increased ethnic

Figure 1 Canonical plot showing cranial relationships of genetically mixed populations, African Americans and Mexican American, to their parent populations. Ellipses enclose an area including 95% of the variation within groups.

diversity. Hispanics are of mixed ancestry, primarily Spanish and Native American. Estimates of Hispanic ancestry normally assess it at around 50% contribution from each group. African Americans too are a mixed group, with up to 20% of their ancestry derived from European sources in some populations. In cranial morphology, as in genetic markers, mixed populations assume intermediate positions between ancestral populations. **Figure 1** using data from the forensic anthropology data bank illustrates this with respect to Hispanics, African Americans, and groups representing parent populations from which they were derived. Intermediate positions of mixed populations are obvious, as is the overlap in distributions, not only with parent populations, but with each other as well.

Most of the intermixture resulting in these hybrid groups occurred in the colonial period. In the United States, many states enacted anti-miscegenation laws, some of which were not repealed until the 1960s. The United States census data indicate that, even now, the vast majority of marriages are within race, despite recent increases in interracial marriage. Biracial individuals pose difficult problems for ancestry estimation.

Unfortunately ancestry estimation has been drawn into controversies concerning whether race should be considered a real taxonomic subdivision of the species. If biological race means anything, it must refer to the inhabitants of the major geographic regions of the world, which are sometimes called geographical races. There has not, of course, ever been any agreement about the number of races that exist because, as was pointed out long ago, the distribution of genes and traits is clinal in nature and there are few abrupt changes as one moves through geographical space. Fortunately, it really does not matter to forensic anthropologists whether race is a valid taxon or not. What we know exists are populations, and populations, even local ones, are often sufficiently differentiated so that their individual members can be discriminated with reasonable accuracy. **Table 2** illustrates this with respect to several different situations. It illustrates that groups that would not be considered different races, such as North and South Japanese, or Arikara and Sioux Native Americans, can nevertheless be assigned to their correct group with high accuracy. It also shows that even groups that can be considered belonging to the same population at different points in time, such as nineteenth- and twentieth-century Whites, can also be discriminated accurately. The results in **Table 2** illustrate that populations are the relevant units and stress the importance of having reference samples appropriate to the situation at hand.

Table 2 Examples of ability to discriminate among populations at different scales, ranging from broad geographic groups to local populations

Comparison	Number of variables	% correct	Reason
BM vs. WM	19	97	Biological race
BM vs. WM vs. CHM vs. NAM	25	96	Biological race
BM vs. WM vs. JM vs. NAM	25	84	Biological race
JM vs. CHM vs. VM	25	80	Ethnicity/language
Arikara vs. Sioux females	7	87	Ethnicity/language
N Japan vs. S Japan males	18	89	Geography
WM born 1840–90 vs. WM born 1930–80	10	96	Time

BM, American Black males; CHM, Chinese males; JM, Japanese males; NAM, Native American males; VM, Vietnamese males; WM, American White males.

Source: Ousley SD, Jantz RL, and Freid D (2009) Understanding race and human variation: Why forensic anthropologists are good at identifying race. *American Journal of Physical Anthropology* 139: 68–76.

On a global level, the geographical patterning of cranio-metric variation has been shown in many instances. Recent analyses have shown that 75% of crania can be correctly classified into their correct population, and 90% classify into a population in the same region. Even on a global scale, the local population is the important unit, but the geographical patterning of local populations is evident.

The task of ancestry assessment in forensic anthropology is to identify the race/ethnic group the person would most likely have belonged to in life. In the United States, races exist as socially defined groups which have been codified by the federal government. That these are official or bureaucratic races does not mean they have no biological meaning. Historically, race has played a large role in mating behavior, although how race has structured mating has changed over time and the interaction among America's groups is complex. Nevertheless, social races have different continental origins and different histories. Since a large majority of matings is within social race groups, preexisting variation is maintained and new variation can develop. It is critically important that forensic anthropologists understand the American population structure in order to make informed ancestry estimations.

Morphoscopic Traits Revisited

Morphoscopic traits were presented briefly in historical context. Their historical use has been based on the assumption that most or all of the members of a particular race will exhibit traits thought to characterize that race, and that variation within a race is minimal. There has been considerable progress on several fronts which promises to make these traits more useful. Problems to overcome in using them include (1) definition, scoring, and standardization; (2) appropriate statistical techniques; and (3) development of population-based data that can be used to investigate variation within and among populations. Traits may be scored as binary, that is, present or absent, and ordinal or ranked. Binary traits typically include the presence or absence of foramina such as parietal foramen, or accessory foramina such as accessory mental foramina, sutural bones such as ossicles in the lambdoid suture, or accessory tori such as the maxillary torus. Ordinal traits are scored into ordered categories, such as absent, small, medium, and large. Neither kind of trait is totally objective, so visual scoring inevitably leads to interobserver variation. Ordinal traits are usually continuously varying traits, which in principle could be measured but are not because measurement is difficult. A browridge, for example, varies continuously from a smooth surface to a large overhanging browridge, but can be arranged on an ordinal scale ranging from absent to large, with intermediate categories. Visual scoring has the advantage of being much faster.

Recent research has taken the first important steps in solving some of the problems mentioned above. Descriptions of traits have been developed to facilitate standardized scoring, and the process of assembling a database of traits is taking place. Examination of variation within and among populations has shown that traits said to characterize certain ancestral groups in lists such as those in [Table 1](#) occur in all major human groups, but in different frequencies. Postbregmatic depression, for example, is said to characterize African ancestry, but in African Americans, it is present in less than 50%, and

occurs in almost 20% of individuals of European ancestry as well. The sharp inferior nasal border associated with Europeans also occurs in 20% of those of African ancestry.

Morphoscopic traits are similar to traditional measurements in many respects. Different populations exhibit overlapping distributions. They perform similarly in discriminating ancestry groups when traits are used in combination in multivariate analyses. They therefore have considerable potential to add another source of data to the difficult task of ancestry estimation, once suitable databases are in place and the software to analyze them developed. These examples make clear that the presence of a single trait will not be an indicator of ancestry.

Estimation from the Postcranial Skeleton

The postcranial skeleton has historically been considered less useful in ancestry estimation than the cranium. The main reason for this attitude is that the postcranial skeleton consists of a number of elements that do not provide a visual gestalt like the cranium does. Consequently, there has been far less research into the utility of the postcranial skeleton. There is, however, no a priori reason to believe that postcranial skeletal variation is less than that seen in the cranium, although one might expect the postcranial skeleton to reflect function to a greater extent than the cranium. Research has tended to focus on specific postcranial features associated with certain groups. Some of these are:

Anterior femoral curvature: There is a general progression in the amount of anterior curvature of the femoral diaphysis as follows: Native North Americans have pronounced anterior curvature, American Blacks the least, tending to very straight femora, and American Whites are intermediate.

Femur subtrochanteric shape: Subtrochanteric shape refers to the shape of the femur shaft just below the lesser trochanter, located on the proximal end. Subtrochanteric shape is normally assessed by means of the index of platymeria, defined as the anterior–posterior diameter divided by the mediolateral diameter, times 100. Low indices, less than 85, are defined as platymeric, meaning that the subtrochanteric region is relatively flat in the anterior–posterior direction. Native North American femora tend toward platymeria, while Whites and Blacks have higher indices. This tendency shows considerable consistency among Native Americans and is therefore often useful in distinguishing Native Americans from Blacks and Whites.

Intercondylar notch height: The distal end of the femur also shows some ancestry variation, at least as far as Blacks and Whites are concerned. A simple measurement that has been proposed is the height of the intercondylar notch with the femur lying on its dorsal surface. Blacks and Whites differ sufficiently to classify them correctly at a rate of about 80%.

General postcranial ancestry variation: The examples given above illustrate that certain specific elements of the postcranial skeleton exhibit sufficient variation to be useful in ancestry estimation. Measurements of postcranial bones are also effective for discriminating ancestry groups in America. [Table 3](#) gives a preliminary comparison of Whites, Blacks,

Table 3 Comparison of cranial and postcranial discriminating efficiency of American Whites, Blacks, and Hispanics, based on nine variables for each data source

Group	Cranial % correct	Postcranial % correct
Blacks	79.4	73.5
Hispanics	67.8	61.9
Whites	77.9	74.9
Total	77.9	74.9

Source of data: Forensic Anthropology Data Bank, University of Tennessee, Knoxville.

and Hispanics for cranial and postcranial measurements. It shows that postcranial discrimination serves almost as well as cranial discrimination.

Statistics and Probabilities

It is not our purpose to go into detail concerning statistical procedures utilized for ancestry estimation, but it is useful to outline their features in general terms. There are two types of probabilities that are useful in assessing whether an unknown individual could be a member of the group to which it is assigned. Both kinds are based on the Mahalanobis D^2 . The posterior probability makes the assumption that the unknown individual belongs to one of the groups to which it is being compared. Therefore, the posterior probabilities must sum to 1.0. The question the posterior probability answers can be phrased as follows: Given that the unknown belongs to one of the groups to which it is being compared, which is the most likely? The highest posterior probability will always be associated with the group with the lowest Mahalanobis distance.

It may be the case that the unknown belongs to none of the groups to which it is being compared or is even similar to any of them, despite having a high posterior probability with one of them. The typicality probability does not assume any group membership and simply answers the question: Does the unknown fit within the range of variation of each group? Typicality probabilities are most commonly based on comparing Mahalanobis D^2 to the chi square distribution, with degrees of freedom equal to the number of variables. It is possible, and in fact happens frequently, that an unknown has a high posterior probability with one of the groups, but falls within the range of variation of several groups, making it impossible to completely exclude them from consideration.

Geometric Morphometry

Geometric morphometry analysis is based on the two- or three-dimensional (3D) coordinates obtained from skeletal landmarks, most commonly from the cranium. Geometric morphometry has been used mainly to address phylogenetic or population variation questions, but is being incorporated into forensic work as a more refined method to address questions of sex and ancestry estimation. Software has been developed exclusively for the purpose of estimating ancestry from coordinate data. Geomorphometric techniques offer some advantages, including visualizing variation, understanding more

precisely what varies, and in separating size variation from shape variation. Those advantages are less clear when the objective is ancestry assessment of an individual cranium. A digitizer is required, not yet part of many forensic laboratories, and, at the present time at least, it is more cumbersome to enter coordinate data into the software. It has also not yet been demonstrated that classification accuracy is superior, although rigorous tests using comparable data have not yet been carried out.

Software

Statistical analyses such as those described above can be obtained using many of the software packages widely available, although one must provide the training sample data against which to compare the unknown skeleton. At least three software packages are available with built-in training samples and are specifically designed to analyze one case. Fordisc 3.1 provides two databases, one specifically designed for US applications, drawn from the forensic anthropology data bank, and one for worldwide applications, using the database of W. W. Howells. Fordisc 3.1 provides the user with many statistical choices, including posterior and typicality probabilities, stepwise selection of variables, analysis with raw, logged, or shape variables, as well as options for saving the analysis and incorporating it into forensic reports. It also provides graphical capabilities.

Cranid provides a more extensive worldwide database than Fordisc, incorporating Howells' plus ten additional samples which fill in some of the gaps in Howells' coverage of the world. Cranid uses 29 variables and does not provide the user with a choice; all 29 must be present. Cranid provides classification by the usual linear discriminant function, as well as nearest-neighbor discriminant function, a useful alternative to linear discriminant function.

3D-id is currently the only software package that performs classification using coordinate data. It makes what would otherwise be a difficult and time-consuming task relatively easy, assuming one can obtain coordinates from the unknown skull. It will perform the analysis on whatever coordinates one obtains, and so is appropriate for fragmentary crania. The analysis can be performed on shape variables only, or one can restore size.

Conclusions and Future Directions

Estimating ancestry from skeletal remains is becoming an increasingly quantitative data-driven enterprise. In part, this is a natural evolution demanded by the increasing complexity of human populations and the questions forensic anthropologists seek to answer. In part, it is demanded by the increasing scientific rigor demanded by the courts, as seen in the Daubert decision, and by legislation following the National Academy of Science report on shortcomings in the quality of forensic science. It is no longer adequate for an expert witness to testify to ancestry based solely on his/her experience. It is now necessary for the procedures used to have gone through the peer review process and have been published, and to have estimates of error rates. This can only be accomplished with procedures

based on appropriate data and statistical procedures. Hence, future endeavors should be characterized by ever-broadening databases and new statistical methods. Data from modern skeletons from Europe, Asia, and Australia are badly needed if ancestry estimation is to reach its potential.

Ancestry estimation now demands the following:

1. It should be based on reference samples appropriate for the populations involved. These are likely to be specific to the country, or even part of the country involved.
2. It must also be based on time-appropriate reference samples. Individuals with twentieth-century birth years differ from those of earlier time periods, in some cases dramatically. Secular changes remain to be investigated in many regions of the world.
3. It should be arrived at using appropriate statistical procedures so that results can be stated in terms of probabilities. These should include both a posterior and typicality probability.
4. Procedures and methods should be fully described.

Facial Approximation

CN Stephan, Central Identification Laboratory, Hawaii, USA

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Anterior The front of the body or a direction toward it.

Exophthalmometer An instrument used to measure anterior positioning of the eyeballs in the skull.

Flower's point The point where the posterior lacrimal crest meets the frontal bone.

Frankfurt horizontal The posture of the head when the two porion (superior most points of the external auditory meatus on each side) and the left orbitale (lowest point of the left eye socket) lie in the same horizontal plane, parallel to the floor.

Freeway space The gap that is present between the upper and lower teeth when the mandible is in its physiologic rest position.

Lateral The side of the body or a direction toward it.

Median plane The section running vertically through the body that bisects it into two equal parts.

Natural head position The posture of the head when an individual is standing with their visual axis horizontal (i.e., parallel to the floor). This plane differs from the Frankfurt Horizontal by $\sim 5^\circ$.

Posterior The back of the body or a direction toward it.

Supine Position of the body, lying down, but face up.

Introduction

In cases where skeletons prove difficult to identify using DNA, dental record comparison, and/or nondental radiographic comparison, and where a skull is present, attempts may be made to predict the facial appearance from the skull (Figure 1). Such procedures are termed 'facial approximation' and are undertaken on the assumption that the skull typography closely relates to the overlying soft tissue of the face. The predicted face is then advertised in the mass media (alongside other case details) with calls for anyone who recognizes the face, or has further information, to contact the appropriate authorities.

In the forensic context, the value of the method is derived from the media release and two possible successful outcomes. First, the facial approximation may help to draw public attention to the case amplifying case exposure and maximizing leads that contribute to case resolution. Second, the predicted face may directly promote recognitions of the deceased individual. The latter outcome is the mainstream aim of facial approximation, but whether or not the method reliably fulfills it is contentious (see the section 'Anatomical Legitimacy and Accuracy of Methods'). Irrespective of its scientific accuracy, facial approximation is justified in a forensic investigation context because it can contribute meaningfully to the investigation, even when the predicted face does not specifically produce recognition. Note here that any recognition of a facial approximation is not grounds for identification. The recognition can only be regarded as tentative, and identification can only be established or denied after further tests with other, more reliable, methods. Facial approximation, therefore, acts as a vehicle for an identification to be made, but it is not an identification method in and of itself.

Until recently, face prediction from the skull was popularly known as facial reconstruction or facial reproduction – terms that are increasingly being abandoned because they overemphasize the scientific basis and accuracy of the methods. Consequently, these terms are also avoided here.

Method History

The first published attempt at facial approximation was made in 1898 by Kollmann and Büchly. In the early 1900s, the method was regarded to communicate only the broad characteristics of a person's face; in particular, the race. This changed to a capability for portrait reconstruction (approximation so close to the appearance of a living person that an unknown individual could be identified) in the 1950s with the Russian anthropologist Gerasimov, and it has since remained the mainstream aim of modern facial approximation methods. The first documented success of the method, in its medicolegal context, was in 1918 concerning a 1916 homicide case from New York (USA), where the method was used to help identify a skeleton as Dominick La Rosa.

For most of its life, facial approximation has been manually executed by sculpting in clay or some other modeling mastic on the skull or a skull cast. However, computerized approaches have emerged over the last 20 years and major revisions of core face prediction protocols have simultaneously taken place. While computer methods have radically changed the way in which methods are performed, the software is not typically commercially or widely available, so manual (sculpting or drawing) methods remain widely employed. Given the methods' high dependency on anatomy and practitioner dexterity, anatomists, anthropologists, and artists have commonly collaborated to undertake the protocols.

Since the late 1990s, facial approximation methods have been classified into one of three categories: anatomical, soft tissue depth, or combination methods (otherwise termed the morphoscopic/morphometric/composition methods; or the Russian/American/composition methods). The 'anatomical' category was designated to concern only those methods that required the construction of the facial muscles (to the exclusion of mean soft tissue depth values). The 'soft tissue depth' category, as the name suggests, was meant to concern only those methods using mean soft tissue depths, and the

Figure 1 An example of a three-dimensional (3D) manual facial approximation, with the corresponding face. Reproduced from Stephan CN and Henneberg M (2006) Recognition by facial approximation: Case specific examples and empirical tests. *Forensic Science International* 156: 182–191, with permission from Elsevier.

‘combination’ category was meant to represent methods that blended the two aforementioned approaches. This system is now recognized to be defunct because mean soft tissue depths underpin all facial approximation methods (even the Russian/morphoscopic/anatomical methods) and because Gerasimov (the recognized founder of Russian methods) actively avoided the construction of the muscles of facial expression. Facial approximation methods, whether executed manually or by computers are, therefore, best described as varying along a continuum: with ‘mean soft tissue depths’ at one extreme and ‘individualized face anatomy’ at the other.

Contemporary Methods

Skull Preparation

For manual methods, the skull is normally duplicated in plaster, acrylic, or some other material so that the original can be spared of any damage and so that it can be used as a reference during the face prediction process. For most computerized approaches, the skull will be scanned using a three-dimensional (3D) scanner, so it can be used within the electronic environment. In all cases, the mandible should be attached to the skull with a ~3–4 mm spacer at the glenoid fossa, to simulate the articular disc of the temporomandibular joint. The anterior teeth of the maxilla and mandible should also be separated by ~2–3 mm to simulate the physiologic freeway space present in the living subject at rest.

Soft Tissue Depths

Except for some computerized approaches that use deformations of existing 3D face meshes to create the new faces, all contemporary manual methods depend on mean facial soft

tissue depths (MFSTD). This includes computer approaches that rely on virtual sculpting.

Soft tissue depths are used to quantify the distance from the skull surface to the facial surface and their means represent average values. Typically the soft depths have been collected for males and females of different ages and ancestral groups and they are represented on the skull so that the practitioner has a rough estimate of how far the soft tissues should extend from the skull surface. The soft tissue depths of many different subjects have been studied over facial approximation’s life span (including embalmed cadavers, fresh cadavers, supine living subjects, and upright living subjects) and a variety of different measurement protocols have also been employed (e.g., needle puncture, B-mode ultrasound, A-mode ultrasound, lateral cephalographs, magnetic resonance imaging, and computed tomography (CT) scans – including cone beam CT).

The small differences that are found between different groups of subjects and studies are often used to justify their separate data logging; however, the practical meaning of these differences are difficult to evaluate because the data are confounded by numerous types of errors (sampling error, observer error, and error inherent to the type of measurement technique employed). Consequently, the small differences between studies and/or their samples may not accurately reflect the real differences between the population groups or the studies.

To date, none of the mechanisms for MFSTD error have been adequately addressed in the facial approximation literature nor has the degree of application error been fully elucidated. Moreover, means have been unanimously employed for what are almost certainly skewed data (measurements can be extremely large but never extremely small or negative), whose central tendencies are better represented by other statistics. These limitations have recently prompted the pooling of data in efforts to provide values that are as comprehensive and accurate as possible, while other central tendency indicators

Table 1 Landmark definitions for the tallied mean soft tissue depths illustrated in [Figure 2](#) and reported in [Table 2](#)

<i>Skeletal landmarks</i>	<i>Definitions</i>
Opisthocranium (op)	Midline ectocranial point at farthest chord length from glabella
Vertex (v)	Highest midline ectocranial point
Glabella (g)	Most anterior midline point on the frontal bone
Nasion (n)	Midline point on the nasofrontal suture
Mid-nasal (mn)	Point on internasal suture midway between nasion and rhinion
Rhinion (rhi)	Midline point at the inferior free end of the internasal suture
Subnasale (sn)	Midline point just below the anterior nasal spine (soft tissue equivalent = midline point of the angle at the columella base where the septum and upper lip join)
Mid-philtrum (mp)	Midline point midway between the base of the nasal spine and prosthion on the anterior edge of the maxillae (soft tissue equivalent = midline point midway between soft tissue subnasale and the vermilion border of the upper lip in the groove of the philtrum)
Labrale superius (ls)	Midline landmark at the most anterior edge of the superior alveolar ridge of maxillae (soft tissue equivalent = midline soft tissue point at the vermilion border of upper lip)
Labrale inferius (li)	Midline point at the most anterior edge on the inferior alveolar ridge of the maxillae (soft tissue equivalent = midline soft tissue point at the vermilion border of lower lip)
Mentolabial sulcus (mls)	Deepest midline point in the groove superior to the mental eminence
Pogonion (pg)	Most anterior midline point on the mental eminence of the mandible
Gnathion (gn)	Midline point half way between the angle and the most anterior and inferior points on the bony chin
Menton (m)	Most inferior midline point at the mental symphysis of the mandible
Mid-supra orbital (mso)	Point on the supraorbital rim at the midsagittal plane of the orbit
Mid-infra orbital (mio)	Point on the infraorbital rim at the midsagittal plane of the orbit
Alare curvature point (acp)	Point ~3 mm lateral to the border of the nasal aperture (soft tissue equivalent = point indicating the most lateral insertion of the nasal wing base into the face)
Gonion (go)	Point on the lateral aspect of the border of mandibular angle where a tangent bisects the angle formed by the posterior ramus border and the inferior corpus border
Zygion (zy)	Most lateral extent of the lateral surface of the zygomatic arch
Supra canine (sC)	Point on superior alveolar ridge superior to the maxillary canine(s)
Infra canine (iC)	Point on inferior alveolar ridge inferior to the mandibular canine(s)
Supra M ² (sM ²)	Point on superior alveolar ridge superior to the maxillary 2nd molar(s)
Infra M ₂ (iM ₂)	Point on inferior alveolar ridge inferior to the mandibular 2nd molar(s)
Mid-ramus (mr)	Point at the center of the mandibular ramus
Mid-mandibular border (mmb)	Point on the inferior border of the corpus of the mandible midway between pogonion and gonion

Landmarks are positioned assuming that the skull is in the Frankfurt horizontal. The soft tissue equivalents overlay the hard tissue positions except where otherwise stated.

Source: Reproduced from Stephan CN and Simpson EK (2008) Facial soft tissue depths in craniofacial identification (part I): An analytical review of the published adult data. *Journal of Forensic Sciences* 53: 1257–1272, with permission from Wiley-Blackwell.

are calculated. These tallied soft tissue depth tables have been calculated across essentially all studies published in the literature and represent the largest sampled standards currently available (see [Table 1](#) for landmark definitions, [Figure 2](#) for positions on the skull, and [Table 2](#) for the tallied soft tissue depths). These mean data hold the advantage that groups are not tenuously categorized, sample sizes are large, and real soft tissue depth values are triangulated upon by averaging data across different measurement protocols.

Noncomputerized Manual Methods

When drawing the predicted face, using soft modeling mastic (such as clay) to sculpt it, or constructing the muscles of facial expression as part of the facial approximation process, it is helpful to attach soft tissue depth pegs to the duplicate skull for reasons described above. If the modeling mastic is much stiffer (as for wax/rosin composites) and the muscles of facial expression are not built, the mastic itself can be used to indicate the depth, removing the need for indicator pegs ([Figure 3](#)). Once mean soft tissue depths are represented on the duplicate skull, the temporalis and masseter muscles are modeled

according to the bony markings that indicate their general locations. Other anatomical structures, such as the superficial temporal fat pad, can also be added according to known anatomical relationships ([Figure 3](#)). In areas where mean soft tissue depths are not available, the depth of the tissue should be interpolated using the neighboring soft tissue depth markers and the practitioner's knowledge of human anatomy. This underscores the importance for practitioners to possess an extensive knowledge of the subject (human anatomy), and preferably, to hold tertiary qualifications in it.

The facial features are then added and generally their order of construction is not important; so long as the deeper structures are represented prior to other overlying, more superficial, components. To replicate typical anatomical positions, the eyeball should be located in the eye socket closer to the orbital roof and lateral orbital wall (each by 2–3 mm). An exophthalmometer should also be used to position the corneal apex ~16 mm anterior to the lateral orbital wall ([Figure 4](#)).

The muscles of facial expression (see Further Reading) can then be added but most of their construction is based on intuitive speculation in accordance with stereotypical patterns. An alternate approach is to use strips of clay to join the soft tissue

Figure 2 Soft tissue depth measurement sites: (a) lateral view, and (b) frontal view. See [Table 1](#) for definitions of landmarks. Reproduced from Stephan CN and Simpson EK (2008) Facial soft tissue depths in craniofacial identification (part I): An analytical review of the published adult data. *Journal of Forensic Sciences* 53: 1257–1272, with permission from Wiley-Blackwell.

depth markers together in a mesh-like scaffold over the skull, removing the need to subjectively speculate on the facial expression muscles ([Figure 3](#)).

The medial canthus (inner corner of the eye fissure) should be placed ~5 mm lateral to the medial orbital wall and lateral canthus ~4.5 mm medial to the lateral orbital wall. The malar tubercle can be used to position both the medial and lateral

canthal ligaments on either side, if it is present, since both canthi roughly fall at the same height and at the malar tubercle level. If a malar tubercle is not present, it can be estimated reliably 10 mm below the frontozygomatic suture. The width of the nose is established by the width of the nasal aperture (=167% of its distance) and the height of the alar wings by the crista conchalis on the inner margins of the bony nose. The projection of the nasal tip and its height can be estimated within several millimeters using various regression equations derived from the skull. The mouth width is equal to 133% of the intercanine distance measured from the lateral aspects of the teeth. The height of the lips approximate the height of the enamel of the front teeth and the lip closure line, in the median plane, sits at about one third of the way up the central incisors. If any unusual anatomy exists on the skull it should be clearly represented in the face since it may provide a trigger for recognition. In the same way, any unusual dental features should be exhibited, so constructing the face in smiling posture may be necessary.

At this point, the skull should be positioned in the natural head position – but note that this does not prevent reference to the Frankfurt horizontal if it is needed for facial feature prediction. Blocking in around the muscles of facial expression will be required, especially when softer modeling materials are used, so that they do not collapse at later face construction stages. If the muscles of facial expression were constructed, sheets of modeling mastic ~4-mm thick are placed over the muscles to simulate the skin and subcutaneous tissues ([Figure 5](#)). The thicknesses of these sheets need to be adjusted to the various face regions to reflect realistic depths. It should not be applied around the eyes, for example, where the skin is extremely thin and the orbicularis oculi muscles are close to the surface. The neck and ears are then added and should be modeled with special attention to the age and sex of the individual. The ear is positioned on the head using the external auditory meatus as a guide – the bony meatus falls ~5–6 mm more anterior and inferior to the soft tissue opening. The ear lobe morphology (attached or free) should be represented in accordance with the most prevalent frequency/type for the ancestral group of the skull in question. Hair can be modeled after its length and texture and form (wavy, straight, etc.), if a sample is recovered from the body disposal site. The final facial approximation should be photographed in black and white so as to down-play color that cannot be predicted from the skull (e.g., color of the irises).

Computerized Methods

The most basic computerized facial approximation methods are 2D and require facial feature images to be selected from a library according to the skull's morphology, and assembled to produce a face. 3D manual facial approximation methods have also been computerized using haptic feedback devices, so that modeling takes place virtually, over a scanned skull using virtual sculpting tools that exert resistance on hand-held devices at the user interface. Although offering some features that manual methods cannot (e.g., X-ray like views of the skull encased in the soft tissue), these methods are largely plagued by the same weakness as their noncomputerized manual counterparts (practitioner subjectivity). Yet another approach is to

automated and objective. A common approach is to scan the skull in question (skull 1), and search a library of skull/face pairs (also called surface references) for an individual with similar skull morphology (skull 2). This surface reference is then deformed to fit the skull in question (skull 2 warped to fit skull 1) and the same or similar algorithm applied to the facial surface map to produce the facial approximation. A modification of this approach is to use a library of skull/face averages for searches, rather than skull/face pairs that represent single individuals, or to deform all reference surfaces of individuals and merge them. A variety of statistical approaches exist for undertaking the deformation and generating the facial approximation (including e.g., regression on principal components, and latent variables regression). These computer methods offer great potential for quantification and standardization; however, they currently suffer from two primary disadvantages: (i) few validation results have been published so their accuracy has largely not been documented as far as facial recognition is concerned; and (ii) the software is often custom-designed so it is not widely available, for example, for commercial purchase. These circumstances may change in the near future.

Media Release

Once constructed, the facial approximation should be advertised on a 'slow' media day to ensure that it receives maximum coverage. Advertisement release on days (or weeks) where other major news events will detract from the article should be avoided. Use of multiple media outlets and formats is recommended and, where possible, the facial approximation

Figure 6 Recognition performance of the facial approximation presented in [Figure 1](#) using 259 assessors. The facial approximation was presented in an array of nine other faces, all shown simultaneously to the assessors. The assessors were asked to decide if the individual representing the facial approximation was, or was not, present in the array; and in the case of the former, which sequence number. The correctly corresponding face was #4 and was recognized above chance rates (5–10%) at statistically significant levels using a Chi-square test ($p < 0.05\%$ as indicated by *). NR, no recognition made. Adapted from Stephan CN and Cicolini J (2010) The reproducibility of facial approximation accuracy results generated from photo-spread tests. *Forensic Science International* 201: 133–137, with permission from Elsevier.

practitioner should retain control over what images are used and have input into how they are presented to maximize opportunities for success.

Anatomical Legitimacy and Accuracy of Methods

Facial approximation methods have commonly been portrayed in the prior literature as highly tuned, accurate, and anatomically legitimate techniques. Over the last 10 years, however, there has been an avalanche of studies that have demonstrated major gaps and shown that many traditional soft tissue prediction guidelines have no underlying anatomical justification and/or are erroneous. Space does not permit for a description of these inaccurate guidelines; however, further information can be found in the recommended reading. Much work remains to be done in the future to cross-check other unverified guidelines and to produce new improved soft tissue prediction rules.

No consensus currently exists on the ability for facial approximation methods to generate purposeful and correct recognitions; however, the repeatability of 3D manual methods is unanimously acknowledged to be problematic. Casework success with the method is reported to be high by some practitioners within the field (60 to ~100%), but there are as many studies showing poor recognition rates of facial approximations as there are studies showing higher rates (see Further Reading). Recognition performance of the facial approximation depicted in [Figure 1](#) is provided in [Figure 6](#) as an example of what can be expected under controlled scientific tests. In evaluating the published literature, readers should be mindful that greater motivators exist for practitioners to share their successful results in this applied field, than to publicly disclose their failures.

The subjective nature of large components of the facial approximation method largely restricts its use to cases where tested

and more objective methods cannot be used (such as DNA, dental comparison, and nondental radiographic comparison). Consequently, the challenge remains to produce a verified face prediction method that warrants classification as ‘scientific,’ and which reliably produces correct facial recognitions in the hands of any practitioner. Irrespectively, the power that current facial approximation holds to focus community attention on a case justifies its use in many circumstances and numerous prior successes of the method in forensic investigations demonstrate the method’s value. Under no circumstances should facial approximation methods be used as a single line of evidence for a formal identification: where a facial approximation is recognized, an indicator for an identity is obtained, and this must be confirmed or denied using other methods.

Glossary

Antemortem Events, materials, or records occurring or collected before death.

Comparative radiography The direct, point-by-point comparison of antemortem radiographs (X-rays) of a missing person with those obtained from the remains.

Decedent The deceased person.

Exclusion A conclusion based on sufficient evidence to determine that the known identity and the decedent are not the same individual.

Failure to exclude A conclusion based on sufficient evidence to determine that the known identity and the decedent may be the same individual but lacking information to make a personal identification.

Insufficient evidence A conclusion that the available evidence is lacking to the degree that no determination of inclusion or exclusion can be made.

Lot number A number assigned to identify a particular group, shipment, or lot of material from a manufacturer.

Morphology The overall shape or structure of the bone.

Multiple corresponding factors The matching of a number of nonscientific physical characteristics and

contextual evidence between a known individual and a set of remains.

Personal identification The matching of a set of remains to a known individual.

Positive identification See scientific identification.

Postmortem Events, materials, or records occurring or collected after death.

Scientific identification The matching of antemortem and postmortem records to sufficient detail in a scientific systematic point-by-point comparison to conclude that they are from one individual to the exclusion of all other reasonable matches.

Serial number A unique set of numbers assigned for the identification of a specific item.

Tentative identification A potential match of a known person to the decedent.

Trabecular bone Also known as cancellous bone or spongy bone, the light and porous bony structure that is found at the end of long bones and within vertebrae.

Visual recognition The identification of a known person by a family member or friend who views the remains of the decedent.

Introduction

Identification of human remains is one of the foremost goals in a medicolegal death investigation. An expedient and accurate identification is imperative to serve both the family of the decedent and the medicolegal system. A personal identification can provide a sense of closure to the bereaved, allows for the release of the body, and is necessary to file an accurate death certificate for the distribution of benefits and to initiate an investigation in cases of homicide or suspicious deaths. Medicolegal death investigation is the responsibility of the medical examiner or coroner, and it is ultimately these medicolegal authorities that must decide whether there is sufficient evidence to establish a personal identification and authorize a death certificate. Therefore, the degree to which a forensic anthropologist is involved in a case is at the discretion of the medical examiner or coroner. As such, it is the duty of the forensic anthropologist to utilize his or her expertise to fulfill these requests.

Personal Identification

Personal identification is the matching of a set of remains to a known individual and it is the ultimate goal in a forensic

investigation. Positive identification is a term that has long been used in medicolegal investigations to indicate an identification based on the scientific methods of fingerprint analysis, comparative dental or medical radiography, and nuclear DNA assessments. However, this terminology is problematic because it implies that a legal personal identification based on methods not considered 'positive' is a weaker form of identification. Thus, in this work, the term 'scientific identification' is utilized to describe an identification that is accomplished through the matching of antemortem and postmortem records to sufficient detail in a scientific point-by-point comparison to conclude that one individual is represented to the exclusion of all other reasonable matches. However, a personal identification can be established via a variety of different processes, including scientific identification, visual recognition of a cadaver, and multiple corresponding factors where there is a preponderance of evidence that matches between the decedent and the missing person. Each of these techniques represents a different level of identification; however, all are considered personal identification and ultimately lead to the release of the remains from the medical examiner's office.

In a majority of cases, someone who knew the decedent can identify the person through visual recognition of the face. This type of identification is a common process in many medical examiners' offices, especially in cases of recent deaths. Either

people who knew the decedent are asked to view the physical remains or driver's license photographs are consulted to visually confirm the identification. This form of personal identification is outside the purview of forensic osteology, however, and is not discussed in detail in this article. In cases where visual recognition is not possible, including those with severe trauma, burning, decomposition, or skeletonization, medical examiners or coroners may consult with a forensic anthropologist to aid in the identification process. Forensic anthropologists can assist in either establishing a scientific identification or contributing to an identification with information from skeletal analyses to limit potential matches to the decedent. Before the discussion of forensic anthropological methods, levels of personal identification must first be defined and addressed.

Types of Personal Identification

Scientific Identification

Scientific identification is a classification that systematically compares known antemortem information of a missing person with postmortem information of the deceased to ensure that they represent one and the same individual. A scientific identification is accomplished when biological antemortem and postmortem information match, with no unexplainable differences, and in sufficient detail to conclude that they represent the same individual to the exclusion of all other individuals. Examples of scientific identification methods include comparisons of nuclear DNA, fingerprints, and dental and medical radiography. Each of these techniques has demonstrated utility in scientifically identifying individuals by focusing on unique aspects of the human body.

A common question from medicolegal investigators, judges, and juries is, 'How many points of similarity are necessary to reach a scientific identification?' Currently, no minimum number of consistent morphologies required for a scientific identification has been established. What this means is that a single point of consistency can represent a scientific identification if considered individualizing. However, practitioners of comparative radiographic methods strive to use multiple morphologies in their analyses.

Although a scientific identification can be considered an optimal method for identifying human remains, it is not always possible or practical. A major impediment to scientific identifications is access to the appropriate resources – the absence of either finances or properly trained forensic experts. A medical examiner or coroner may not have access to forensic professionals trained in methods suitable for scientific identifications. In other cases, financial constraints may prevent medical examiners/coroners from utilizing such consultants or laboratory analyses. Lack of time to process such cases may also preclude a scientific identification. Both families and funeral homes can apply significant pressure to medicolegal investigators for the release of the decedent, and many scientific identification techniques can take time to complete.

A final limitation that may prohibit a scientific identification is lack of appropriate or adequate antemortem records. Although dental and medical radiographs seem commonplace, there remains a large segment of the population that has never had a radiograph taken. In other cases, the antemortem

radiographs may be difficult or impossible to locate or the quality of radiographs may be too poor to be useful. As a result of these potential barriers, many medical examiner's or coroner's offices rely on more expedient and cost-effective methods to personally identify human remains.

Multiple Corresponding Factors

In cases where there is no scientific antemortem information available for comparison between the missing person and decedent, medical examiners or coroners may rely on multiple corresponding factors to support a potential identification. This approach utilizes contextual evidence in conjunction with a number of physical features to arrive at an identification. Contextual evidence may refer to the location where the decedent was found and personal effects associated with the remains, whereas physical features may include the biological profile, tattoos, piercings, dental characteristics, surgical alterations, and mitochondrial DNA. These identifications are made by a preponderance of matching nonscientific or non-unique characteristics and vary in strength depending on the number and the quality of factors contributing to the identification. Furthermore, it is the combination of distinctive physical features and contextual evidence that makes an identification via multiple corresponding factors a personal identification. For instance, if the remains of an edentulous female in her mid-80s with a hysterectomy and evidence of a healing hip fracture were found in the secured home of an elderly woman of that same description, there would be multiple physical and contextual characteristics to indicate that the decedent and the woman who lived in the home were the same person. This identification by multiple corresponding factors is much stronger than an identification of a young woman found in a public location and identified through visual comparison to a driver's license or passport found with the remains.

Methods of Scientific Identification

Personal identifications, as outlined above, can be made at several levels of confidence, with a scientific identification being the gold standard. Although there are a number of methods that forensic anthropologists can utilize to contribute to the identification process, comparative medical and dental radiography are the only scientific techniques that can establish a scientific identification.

Comparative Radiography

Comparative radiography is the point-by-point comparison of antemortem radiographs of a missing person with the corresponding postmortem films of the decedent. To control for differences caused by radiographic imaging, it is essential that the postmortem radiographs simulate the antemortem films as closely as possible in both scope and angulation, making sure to highlight the same skeletal features. This can be particularly challenging in cases where remains are in a state of decomposition or skeletonization that make them more difficult to appropriately position. This may require the anthropologist

Figure 1 The postmortem (bottom) dental radiographs highlight the same dental restorations and simulate the antemortem (top) radiographs for a scientific identification.

to take many sets of postmortem films, but without such efforts a radiographic comparison is not possible.

Dental radiographic comparisons

Radiographic comparisons fall into two broad categories – dental and medical. With annual dental examinations becoming the standard of care, the likelihood of an individual having antemortem dental radiographs is quite high. Additionally, the mineral composition of teeth makes them extremely resilient to postmortem damage, decomposition, temperature extremes, and fire destruction. Thus, both antemortem and postmortem dental information are likely to be available for comparison. Furthermore, the variety of dental structures and dental treatments provides numerous features that, when taken in combination, can offer an individualizing suite of characteristics. Features of dental radiographs that can be used in forensic identifications include crown and root morphology, tooth angulation, bone trabecular patterns, maxillary sinus morphology, the location and morphology of dental restorations, cavities or other dental pathologies, and missing teeth (**Figure 1**). Beyond the tooth structures visible in dental radiographs, other anatomical landmarks are also used to corroborate an identification. The increasing use of panoramic radiographs provides even more features for comparison, including the nasal aperture, the nasal septum, nasal conchae, inferior and lateral borders of the eye orbits, and mandibular morphology (**Figure 2**).

Medical radiographic comparisons

Although dentition is the most common feature used for positive identification, any area of the body documented in antemortem radiographs could potentially be employed for such purposes.

Figure 2 A panoramic radiograph showing maxillary dentition, nasal aperture, septum, conchae, and eye orbits.

In medical radiographic images, overall morphology of the bone, anatomical landmarks, trabecular patterns, orientation, placement of foreign materials including bullets or shrapnel and surgical implements, skeletal anomalies, pathological conditions, and evidence of traumatic injury can be used. Relatively common areas for radiographs to be taken during life include the head, chest, and limbs.

An antemortem radiograph of the head can be extremely helpful for a forensic anthropologist attempting to make an identification. Beyond the potential of using the dental information contained within such a radiograph, it has been demonstrated that the frontal sinus is a structure that has a unique morphology in all individuals (**Figure 3**). Located above the eye orbits in a person's forehead, the bilateral frontal sinus is a hollow air cavity that is commonly asymmetrical and highly variable between individuals. Thus, it is an ideal structure to be used in a scientific identification. In the case of young individuals, however, the frontal sinus may not be fully developed and may not be available for comparison.

Figure 3 An anterior-posterior radiograph of the cranium with the unique morphology of the frontal sinus highlighted in the red box.

The chest is another common anatomical region for comparative radiography. While antemortem radiographs are often taken to visualize the lungs or other organs, skeletal features may be visible and useful for comparative purposes. Studies have shown that features of the vertebral column are individualizing and can be used for scientific identifications. Similar to dental comparisons, it is the suite of features of the vertebral column that makes it personalizing (Figure 4). Areas that are visible on radiographs and can be used in a point-by-point comparison include the shape of the vertebral bodies, the spinous processes, the transverse processes, the pedicles, intervertebral disc space, and any arthritic lipping or other degenerative changes. Studies have shown that features of the vertebral column outlined above are consistent in radiographs that have been taken decades apart and prove the utility of such radiographs for use in scientific identifications.

An interesting application for the use of anterior-posterior chest radiographs is the identification of missing American soldiers from past military operations at The Joint POW/MIA Accounting Command Central Identification Laboratory (JPAC-CIL). Owing to tuberculosis concerns, chest radiographs became a routine procedure across the United States Armed Forces in 1942, unknowingly creating an archive of antemortem radiographs for American soldiers. Thus, forensic anthropologists are utilizing these archives to help identify the remains of soldiers that went missing during the Korean War.

In many skeletal radiographs, the details of the trabecular bone can be seen and used in the comparison. As bone is a living tissue that is constantly remodeling, the consistency of such structures through the passage of time may be considered a concern. If the trabecular bone structure changes over time, an individual could be wrongfully excluded. However, studies of trabecular patterns have shown that the morphology is maintained over time and through subsequent remodeling events. It has now been demonstrated that even with age-

Figure 4 Antemortem and postmortem radiographs demonstrating consistency in shape and location of spinous processes, pedicles, and centra.

related bone loss, trabecular bone patterns can provide individualizing information to aid in identification.

The role of experience

While forensic anthropologists can provide important contributions to personal identifications using comparative radiography, it is of utmost importance that the individual has been trained in comparative radiographic comparisons and is aware of the limitations of the method and their experience in making identifications. A number of studies have demonstrated that the interpreter's experience level directly affects his or her ability to make a correct identification. To the untrained eye, standard anatomical landmarks may be identified as consistencies between antemortem and postmortem radiographs. In reality, however, these features are relatively consistent between most individuals and are not always individualizing. Forensic anthropologists with training and experience are able to differentiate the distinctive skeletal features that will be useful for a personal identification from those that are commonplace. This underscores the importance of appropriate forensic training and experience for practitioners to accurately make scientific identifications.

Validation studies

Historically, scientific identifications have been admissible in the court of law; however, new standards for expert testimony have encouraged the publication of validation studies for various types of dental and medical radiographs for scientific identification purposes. Therefore, many validation studies have either been published or are forthcoming. To test the utility of various skeletal structures, researchers investigate its uniqueness within a sample population or practitioners' ability to utilize the structure to match simulated antemortem and postmortem radiographs. By establishing known error rates and statistical probabilities of the antemortem and postmortem radiographs originating from a single person, forensic anthropologists can confidently report on the accuracy of their methods in the court of law.

Possible Conclusions in a Scientific Identification

In every scientific identification consultation, the forensic anthropologist may reach one of three possible conclusions – a personal identification, an exclusion, or an insufficiency of evidence for determination.

Identification

To establish a scientific identification, a forensic anthropologist must perform a systematic detailed comparison with the goal of finding consistency in the overall skeletal morphology and in unique or identifying features. If a significant amount of time has passed since the antemortem radiograph was taken, there may be noticeable differences between the two sets of radiographs. Such time discrepancies must be taken into account. Alternatively, any noticeable differences between radiographs must be explainable by the passage of time or slight differences in angulation of the image. If one of these explanations cannot be used to describe a discrepancy between sets of radiographs, the antemortem and postmortem records are likely not from the same individual, and the potential match may be excluded.

Exclusion

In the case of an exclusion, sufficient evidence is available from the antemortem records to conclude that the presumptive individual and the decedent could not possibly represent the same individual. This results when disparities between antemortem and postmortem records cannot be explained by the passage of time, by differences in radiographic angulation, or for any other reasonable cause. The exclusion of a missing person means they are eliminated from the list of potential matches and it is necessary for new potential matches to be located and tested. Although the exclusion of a potential identification may send medicolegal investigators back to the field to gather more information, it is an important contribution toward the proper identification of the deceased, as it narrows down the list of possible matches.

Insufficient Evidence

At times, antemortem records are unavailable, too generalized, of poor quality, or too far removed in time to be useful. In such cases, a forensic anthropologist is unable to determine whether the antemortem and postmortem records originated from the same individual. This includes situations where the available antemortem information is consistent with the postmortem evidence from the decedent; however, the consistent features are not individualizing to the extent required to make a personal identification. Essentially, the forensic anthropologist is unable to exclude the owner of the antemortem records from the list of possible identities of the decedent but cannot definitively make a match. As an example, if no antemortem medical or dental records are available, the forensic anthropologist may only be able to comment on whether the biological profile of the skeletal remains is consistent with those of the potential decedent.

In cases where the antemortem data simply do not exist, or are of poor quality, the forensic anthropologist may be unable to either support or reject the hypothesis that the decedent and the remains represent the same individual. At this point in an analysis, a forensic anthropologist cannot contribute any further until investigative work is able to locate more complete or better quality antemortem records that may be used to retest the hypothesis that the missing person and the decedent represent the same individual.

Methods Contributing to Identification

While comparative radiographic techniques are the only anthropological methods that can directly identify a decedent, there are a number of analytical techniques a forensic anthropologist can employ to contribute to the identification process. These efforts generally help by limiting the list of potential matches to the decedent, moving the investigation closer to a personal identification.

Biological Profile

Acquiring antemortem records is a critical first step toward making an identification; however, this requires some idea of the identity of the deceased. This would be a person or a list of reported missing persons that are potential matches to the decedent. Therefore, the forensic anthropologist may be consulted to assess the biological profile of the remains in order to narrow the list of potential matches. Once a short list of possible matches has been compiled, antemortem records and other identifying information may be gathered for these individuals. A biological profile consists of the sex, age, ancestry, and living stature of an individual. In cases where soft tissue is unavailable for visual determination of these characteristics, a forensic anthropologist can assess particular skeletal morphologies to estimate each feature of the biological profile. A report of the biological profile and any unique skeletal features of the individual may help investigators identify potential missing person matches to the decedent. Once a possible identity is ascertained, a forensic anthropologist may be asked to employ the techniques outlined above to obtain a personal identification.

Skeletal Pathologies and Anomalies

In cases where antemortem radiographs are not available, photos or descriptions of individualizing features may lead to an identification through multiple corresponding factors. Similar to comparative radiography, this requires a possible missing person match and cooperation with those that knew the decedent to obtain information on potentially identifying features. Although medical records may not contain radiographs for comparison, they can still be used for information on dental procedures, such as extractions and root canals, or medical intervention, including fracture stabilization or surgeries that may be reflected in the skeletal remains. Additionally, skeletal anomalies, such as a cleft palate or scoliosis, can also be used as identifying features. If soft tissue is still present on the decedent, distinctive freckles, birthmarks, or tattoos may also be used to corroborate a

Figure 5 The antemortem (left) and postmortem (right) radiographs of a surgical plate and screws used to stabilize a fibula after injury.

Figure 6 A postmortem radiograph of an individualizing series of sternotomy wires.

potential identity. If one of these features is particularly rare or unique, it may serve as strong evidence of a decedent's identity. In most cases, however, a forensic anthropologist must be cautious in relying on such characteristics for identifications because any single characteristic may not be unique in isolation.

Figure 7 A cervical vertebra with a surgical plate displaying a lot number.

Surgical Implants

Beyond biological features of an individual, identifications may result from the analyses of objects found within a person. As previously discussed, dental restorations in the form of fillings, root canals, and crowns can display a unique morphology useful in comparative radiography. Other foreign objects within the body can serve a similar purpose. The placement of metal plates, screws, or rods for bone stability after traumatic injury or the persistence of a bullet or shrapnel can help individualize a decedent (Figure 5). Sternotomy wires used to suture the sternum after open-heart surgery are especially useful. Unlike other surgical implants that have a particular shape and often standardized placement within the body, sternotomy wires are pliable and are hand-twisted making a series of wires entirely unique (Figure 6). If antemortem medical radiographs exist of such structures, a radiographic comparison may be possible leading to a scientific identification.

An additional benefit to surgical implants is the potential for obtaining individualizing information to reach a tentative identification. Many surgical implants are etched with the company's logo in addition to a serial or lot number (Figure 7). In some cases, these serial numbers are unique and can be traced to the individual in which the implement was placed. In cases where only a lot number is present, it may be possible to track that number to a batch of implants, time period, and the hospitals to which they were sent. Through collaborative efforts by the forensic anthropologist, surgical supply companies, and hospitals, it may be possible to produce a list of potential patients that received the medical implant in question. The forensic anthropologist is often responsible for the careful removal of the surgical implement to minimize damage to both the bone and the implant, and to retrieve the important information.

Figure 8 The laboratory equipment utilized to perform a skull-photo superimposition.

Figure 9 A successful skull-photo superimposition showing the matching of skeletal structures to facial features, including the missing left central maxillary incisor.

Photographic Imaging Techniques

Although they are not often considered a form of identification, techniques that utilize photographic images can be used to either exclude a possible identification or support its continued inclusion in a list of potential matches. Skull-photo superimposition is a method in which an electronic mixer is

used to superimpose the photo of a known individual onto the skeletal remains of the decedent (Figure 8). These two images are expertly manipulated and scaled to align relevant physical features and assess facial proportionality (Figure 9). Features that can be aligned between the fleshed face and the skeletonized cranium include the teeth, the outer edge of the eye orbits, the bottom margin of the nasal aperture, the midpoint of the chin, and the openings for the ear canals. If these points can all be brought into alignment, effectively superimposing the photograph onto the cranium, the two remain a potential match. Alternatively, if the features cannot be aligned, the presumptive identification may either be excluded or a conclusion of insufficient evidence made if the images lack clarity.

The use of photographic superimposition may also be applied to cases of living individuals. Specially trained forensic anthropologists use photo-photo or photo-video superimpositions to compare images of a perpetrator and a suspect to determine if they could represent the same person. A methodology similar to skull-photo superimposition is employed, where the two images are aligned to compare facial proportions; eye shape and spacing; nose size and shape; ear location, size, and shape; lip morphology; and any additional unique features such as freckles, moles, or scars.

Conclusion

Medical examiners and coroners are charged with the important responsibility of legally identifying a deceased individual. This may require consultation with forensic specialists in other fields of study who have expertise in various methods of personal identification. As specialists in skeletal biology and human variation, forensic anthropologists are experts in the assessment of a biological profile and are proficient in

distinguishing atypical or unique skeletal features that can be used in an identification. Furthermore, those experts with additional training in comparative dental and medical radiography can utilize scientific methods to affect a scientific identification. In every case, a forensic anthropologist should employ all of their education and experience to ensure that a proper personal identification is made. This also means that forensic anthropologists must know the boundaries of their own knowledge and the limitations of the methods they are employing. As personal identification legally confirms a person's death and is necessary for the execution of a death certificate and the resulting distribution of benefits, a non-identification is always superior to a misidentification. Thus, it is of great importance that forensic anthropologists pursue thoughtful and thorough consideration in every case.

Introduction

This article provides a summary of some bone pathologies that are useful for forensic anthropology (FA), focusing on aspects related to identification (ID). Antemortem trauma is also reviewed, with an emphasis on its benefits for forensic anthropology, particularly in cases of child abuse or torture.

During the reconstructive phase of identification, forensic anthropologists – besides generating a biological profile of the victim – have to read the skeleton and/or body in order to identify factors of individualization. These factors make it possible to discriminate one individual from another; no two skeletons are alike.

Among the particularities of skeletons with the potential to discriminate, anthropologists must be particularly careful to distinguish between morphological and pathological traits. This is important because some of the so-called discrete traits – that is, nonmetric skeletal traits – can be misdiagnosed as lesions. Examples include sternal perforation or septal aperture in the humerus. The frontiers between morphology and pathology are fluid, and only solid determinations of anatomical variants can lead to reliable diagnoses.

Anthropologists also deal with paleopathology, which is the use of sources such as skeletons and iconography to study the history and evolution of diseases, although skeletons are the common elements between FA and paleopathology. However, while in FA one has the possibility to verify the diagnosis, this almost never occurs with past populations. The bridge between these two sciences is indeed important. Only with a strong background on reading and interpreting dry bones would one be able to recognize some pathologies.

Yet, in FA, the most important issue is not the diagnosis of the pathology itself, but more importantly the description of their consequences on the individual's life. A particular gait or an abnormal limb shape will be more easily recalled and/or confirmed by the relatives of the victim than the pathology itself. Spondyloarthropathy (SP) is a good example of this: although the family might not know the name of the disease, they may recognize the effects of this disorder on the limited mobility of the individual.

On the other hand, one has to bear in mind that forensic anthropologists can deal with cases where the bones are not dry. This means that a paleopathology background is not enough for reading the variety of bone lesions that can occur in FA. A broader knowledge is necessary, namely an understanding of

the whole reaction and healing process, including the bones, the vessels, muscles, ligaments, and skin. The interpretation of hemorrhagic signs, such as discoloration or other chromatic alterations and the recognition of ossified cartilages, can escape the attention of those who deal exclusively with dry bones.

While paleopathology is fundamental, reading lesions in FA is not a simple transposition of paleopathology techniques to more recent remains. Precisely because the bones are more recent, they may also preserve other tissues besides the hard ones; the main object of analysis can therefore be quite different between paleopathology and FA. Yet, some principles/rules are absolutely identical, the most important of which is that when trying to infer pathologies from the bone, the absence of evidence is not evidence of absence. Only some pathologies leave signs on the skeleton, which is one of the last systems of our body to respond to an aggression. (Aggression here refers to the action of any type of agent, physic or not, exterior to the body. Bacteria and virus are also examples of aggression agents.) Chronic diseases are much more likely to be visible postmortem; the exceptions are those diseases that initially focus on the bones themselves, such as a primary bone neoplasia. As a consequence, the majority of acute diseases will be imperceptible upon a simple visual examination and may thus escape the attention of the expert. Simultaneously, this implies that a majority of causes of death cannot be inferred from the skeleton.

It is important to recall that a lesion is not a pathology, but it is a conjunction of lesions in a skeleton, their pattern, distribution, and type which can eventually lead to the diagnosis of a pathology. Differential diagnosis, which is always mandatory, will be done on the basis of these lesion characteristics.

Bone Pathology

Types of Lesions and Bone Reaction

To interpret a lesion one has to understand bone reaction as an aggression against the tissue. While alive, bone tissue will react by bone destruction (osteoclastic activity) and/or bone formation (osteoblastic formation). Pathognomonic reactions are very rare; that is, bone is monotonous in the way it reacts to external agents, which can limit the diagnosis of a specific disease, particularly when the skeleton is incomplete (common in forensic cases).

Keeping lesion description separate from lesion interpretation is a delicate balance. In any formal report, the description of the lesion should be detailed enough to permit a second opinion by another expert. An objective, descriptive approach is useful: location, size, type of lesion (e.g., lytic and exostosis), and pattern distribution within the skeleton (unifocal or symmetric, for instance) are obligatory (Table 1).

In the eventuality that a missing person is known to suffer from a disease easily diagnosed by skeletal analysis (e.g., tuberculosis), the fact that the skeleton does not display any signs of that disease does not necessarily mean that the individual did not suffer from that illness. The developmental stage of the disease may be too early in the cycle to permit a full diagnosis: initial stages may be much less susceptible to affect bone and it will also depend upon the type of disease. For example, osseous TB will be more visible than a secondary bone lesion due to pulmonary TB.

The epidemiological data on the various disorders which affect the skeleton can be paramount to the forensic case by helping to clarify issues such as postmortem interval, sex, and age. A very advanced and therefore severe case of spondyloarthropathy will probably date before the use of corticoids; osteoporosis is more prevalent in women after the menopause; Paget's disease is more frequent in Europe than in Asia. The type of treatment, especially surgical intervention or a prosthesis, might also help a lot to assess the chronological context.

Pathologies Useful for Forensic Anthropology

Among congenital and genetic conditions, while some are rare but obvious (as is the case of nanism and acromegalia), others, such as congenital fusions, supernumerary bones or their congenital absence, parietal foramina enlargement, and the failure of fusion of the neural arches, might require a differential diagnosis with other pathologies. Other conditions, such as cleft palate, craniosynostosis, or bone hypoplasia, which cause limb deficiencies might be easily recognizable by their consequences on face physiognomy or gait, respectively, by both the expert and the victim's relatives.

Table 1 Lesions' description

Lesions' location	Indicate the affected bone Specify the site on the bone, related to the anatomical position: Shaft, epiphysis, metaphysis; anterior/posterior, medial/lateral aspects; superior/medium/inferior third, etc. Measure the distance (cm/mm) from lesion to reference anatomical points: Midclavicular line, nearest joint or epiphysis, etc.
Type of lesion	Lytic, hypertrophic, depressed, with cloaca, porosity, necrotic bone, etc.
Distribution pattern	Unifocal, symmetric, randomly distributed, diffuse widely distributed
Size and shape of the lesion	Overall shape Pyramidal, elliptical, spherical Size (cm/mm) according to shape Height and base, diameter, perimeter, width, etc.

Metabolic disorders, such as rickets (lack of vitamin D) and scurvy (lack of vitamin C), produce reactions in the bone which, in conjunction, can allow their diagnosis. While these disorders are very rare in developed countries, in the context of crimes against humanity, a forensic anthropologist has to be aware of the possibility of finding them in less-developed countries. Rickets is characterized by a deformity in the long bones, particularly those of the lower limbs, accompanied by bone porosity. In relation to scurvy, though it requires a prolonged deprivation of vitamin C and is therefore rare, when present, it attacks metaphyses which can easily fracture.

Osteoporosis is a well-known metabolic disease affecting in particular women past middle age. The loss of bone is perceptible by vertebral compression, or, in more severe cases, by vertebral fractures. Kyphosis is a symptom recognizable by relatives. In the appendicular skeleton, fractures of the forearm and the femoral neck are the pathognomonic signs. Bone densitometry and X-rays are valuable tools for the diagnosis which, in the case of preexisting antemortem elements of comparison, can facilitate positive ID. Furthermore, the fragility of the bones and their low weight can be good clues to this disease, although they can be confounded with taphonomical effects or even by other diseases, such as rheumatoid arthritis and spondyloarthropathy.

Concerning infectious diseases, bacterial infections are much more likely to lead to bone lesions than viral ones. Some infections may be identified, as with periostitis, where only the more external bone layer (the periosteum) is infected. In more severe cases, when the infection goes deeper into the medullar cavity of the bone, osteomyelitis results. This condition is more readily identifiable since necrotic bone, bone enlargement, and cloaca are almost unequivocal signs. Furthermore, it would be difficult for someone to suffer from osteomyelitis without a close relative knowing about it; moreover, the infection will typically be only in one bone and thus the pathology will be specific. Other infectious diseases which can be specifically diagnosed in the bone include tuberculosis, brucellosis, leprosy, and treponemostosis.

Mycobacterium tuberculosis (and also *M. bovis*) mainly affects spongy bone, leading to the destruction of vertebral bodies (mainly adjoining thoracic ones), sometimes producing a kyphosis. The long-bone epiphyses can also be involved as well as the ribs.

Rhinomaxillary syndrome is one of the main features of leprosy: the loss of upper anterior dentition and destruction of the palate. Bones of the extremities, typically distal phalanges, are also affected. Physiognomic key traits will be noticed and remembered by the familiars of the persons who suffered from leprosy which will facilitate identification.

Congenital syphilis is a type of treponemal disease which leaves typical marks on the bones, in particular on the skull with characteristic aspects due to caries sicca. When the postcranial skeleton is implicated, normally it is one long bone such as the tibia, whose enlargement (the so-called saber shin, which is more common in yaws) will be observed in the absence of antibiotic treatment.

Finally, brucellosis appears in the skeleton with osteoarticular localizations typically in the superior anterior portion of the lumbar vertebrae. This very contagious disease might be confounded with TB. Its forensic relevance relies on the vector

of contagious contact with animals and its higher prevalence in the Mediterranean countries.

Regarding degenerative disorders, osteoarthritis (OA) is the most common articular degenerative disease, affecting a significant percentage of individuals after the fourth decade of life. Osteophytes, porosity, and eburnation are the lesions which, particularly in conjunction, will allow the diagnosis of OA. Although the more common a disease is, the less chances it has to provide a positive ID; OA is nevertheless a paradigmatic example of the contrary. The fact that no two individuals can develop exactly the same osteophytes, of the same size, shape, and location, makes them valuable factors of identification, whenever antemortem X-rays are available to perform the mandatory comparison. The compatibility among at least four different points, among the ante- and postmortem X-rays, is considered to provide a positive identification.

Within nonarticular degenerative diseases, enthesopathies, now more appropriately designated as enthesal changes, play a major role in what FA is concerned. The lesions on the insertion sites of muscles, tendons, and ligaments can function as markers of occupational stress providing clues for the amount of physical effort done by certain individuals. Repetitive microtraumas on the sites of muscular insertions will provoke calcifications. Enthesal change on the tendon insertions of the Achilles, patella, or the calcification on the head of the ulna where triceps brachial inserts are some good examples. However, attention should be paid since some diseases, such as diffuse idiopathic skeletal hyperostosis (DISH) or SP, can cause these types of lesions; therefore, the diagnosis is not straightforward.

Moving now to rheumatic disorders, SP, with the typical sacro-iliac ankylosis and the ascending fusion of the vertebral column, when found would mean that the individuals under analysis were very limited in their motion; the bones will tend to be more fragile and light because of this. DISH is recognizable in the skeleton by a flowing right antero-lateral ligament ossification in the vertebral column. Symmetrical and evident enthesal changes in the appendicular skeleton are also key elements for the diagnosis. DISH is differentiated from SP because in DISH the vertebral bodies are not fused to each other and the intervertebral space is kept. This disorder, although asymptomatic, is associated with obesity and diabetes. Finally, a malignant neoplasia might have much more potential to provide ID, whereas benign lesions, such as button osteomas, can work as factors of identification in case there are antemortem examinations for comparison. Typically, the rarer a lesion is, the more chance it has to promote identity. Exuberant malignant neoplasms, with their destructive and irregular pattern, will be valuable tools to ID, especially because they are age dependent.

Further sources where bone pathologies which may help identification are discussed and listed in the Further Reading.

Antemortem Trauma

Besides a violent fracture, stress or fatigue fractures, which originate from the application of repeated forces of low magnitude over a period of time, can be frequent within gymnasts, athletes, ballet dancers, military recruits, and others who

engage in repetitive physical activity. Stress fractures may assist with identity or with suggesting an occupation or hobby. Spondylolysis, which is a complete separation between the vertebral body and the corresponding arch of the vertebra, is the best-known type of stress fracture. Finally, pathological fractures have also to be taken into account, where a disease or condition, such as osteoporosis, rheumatoid arthritis, neoplasms, or others, weakens the bone and leads to a fracture.

For FA, a fundamental question remains concerning antemortem trauma: How long did the individual survive the lesion? Not only does this assist with the timing of the event and possible identification or elimination of the person in question, but also the forensic relevance of this issue is significant since it has serious legal repercussions.

Antemortem lesions do not have the same meaning in FA and in forensic pathology (FP), as illustrated in [Figure 1](#). In FA, antemortem trauma will be recognizable macroscopically or microscopically (the osteogenic response is able to be seen sooner by microscopic analysis). By a simple visual inspection, callus formation (gross enlargement of a portion of bone at the fracture site) ([Figure 2](#)) and periosteal reaction or the rounding of fracture margins will clearly indicate antemortem fracture. Yet, typical bone responses (osteoblastic, osteoclastic, line of demarcation, and sequestration) can only be seen through a microscope. It should be noted that distinguishing between postmortem and antemortem wounds with little survival time is still difficult to do histologically. It is indisputable that woven bone must be present (usually not visible before 2 weeks) to establish a specific antemortem period or even to determine an antemortem origin. It has to be emphasized that even radiology may miss fractures which histology, afterward, detects; histology always provides a more precise dating.

Figure 1 The different concepts of perimortem between pathology and anthropology.

Figure 2 Misaligned, although treated, antemortem fracture of the femoral neck from an identified individual of a recent skeletal identified collection.

Recent studies have yielded important data on the important question of healing after trauma. After only 6 weeks, osteoclastic and osteoblastic activities were reported in healing cranial trauma. Interpretations of time elapsed since death evidence benefit from ongoing research on dry bone, such as in pilot studies on the detection of microscopic markers of hemorrhaging and wound age on dry bone. Whereas unequivocal signs of long-term survival can be reliably determined, short-term survival continues to be problematic. Recently identified skeletal collections are able to provide important data on this issue, since the hospitals still keep the patients' files concerning antemortem traumas (Figure 2).

Antemortem registration should be as complete and objective as possible (Table 2).

The value of antemortem trauma for forensic anthropology can be systematized as follows:

- Identification
- A possible contribution to the determination of the cause of death
- Diagnosis of child abuse
- A tool to document human rights violation

The benefits for identification are obvious and well known since antemortem fractures are undoubtedly good factors of individualization. When treated with surgical intervention, the

chances of ID are increased. Concerning the second advantage, although the signs of bone remodeling mean that the injuries did not cause the death, it is possible that subsequent complications might have caused it. The last two benefits of antemortem trauma for FA are discussed below.

Child Abuse

Skeletal damage in child abuse is a new and recent challenge in antemortem trauma. If cranial injuries are the most frequent cause of death in child abuse, it is the skeleton that brings the case to the health-care system and to a possible diagnosis with the antemortem lesions assuming a role of extreme relevance.

Forces that twist or create torsion in a bone can shear the periosteum from the bone, even without a fracture, and cause bleeding with new bone formation over the subperiosteal hematoma in 1–2 weeks. If it is incipient, it can be seen only in radiographs as a line parallel to the shaft of the cortical bone; if stronger forces are applied, the new bone growth can be observed in a visual examination.

Limb fractures, in the metaphysis or epiphyses, whether in the bone or in the periosteum, are often diagnosed in ossified tissues and are highly characteristic of child abuse. Forces of violent traction, or torsion of the limbs, are responsible for these injuries.

Epiphyseal–metaphyseal lesions, considered diagnostic of child abuse, because of the partial or complete dislocation of the epiphysis, the metaphysis, and a thin layer of metaphyseal reaction, can be seen in radiology. Because of the small size of the fragments, these are occasionally undetectable in a routine analysis. An X-ray is crucial to identify these fragments and to orientate the FA examination. Diaphyseal injuries consisting of spiral fractures, caused by the twisting of the bone, and transverse fractures, caused by a direct blow or bending of the bone, are easier to observe than the epiphyseal–metaphyseal lesions. The range of healing stages, from the periosteal thickening to the callus, can be observed; the lack of treatment may be indicated by possible angulation or inappropriate consolidation of the fracture elements. Although a spiral fracture strongly suggests child abuse, it can be accidental.

The literature is controversial on cranial antemortem injuries in children. If present, they can be assumed as a putative sign of child abuse, as accidental trauma in these ages is extremely rare. Falls in domestic accidents, such as from a chair or from a bed, normally do not cause bone damage and, therefore, they rarely represent the primary cause of death in children. The parietal and temporal bones break more frequently; when severe enough, they may extend to the base of the skull.

Rib fractures in a child older than 6 months, if not a victim of a traffic accident or a major trauma and in the absence of any bone disease, strongly point to child abuse. Rib fractures can be multiple or bilateral, and of different ages, but are usually located in the posterior arch near the costo-vertebral junction. The classical aspect is the observation of a vertical line of sequential callus down one or both posterior rib arches, near the head of the ribs, having the appearance of a 'string of beads' (Figure 3). This can be simply palpated and dissected in an autopsy or observed in an FA examination. In many forensic settings where radiologic facilities are not available, the direct observation of those calluses is sometimes the first alert for a child abuse case (Figure 4). Rib fractures are often better

Table 2 Antemortem trauma registration

<i>Antemortem feature</i>	<i>Registration</i>
Bone location	Indicate the affected bone See the same item in Table 1
Severity	Light, medium, severe
Trauma etiology	Blunt/sharp/perforated/mixed/impossible to determine
Trauma mechanism	Tension/compression/twisting or torsion/bending, angulating/shearing/mixed/impossible to determine
Trauma classification according to severity of distortion	Simple fracture/comminuted fracture/compound open fracture/refracture
Description of fracture	Complete/incomplete, direction, orientation, single line/irradiating/'spider fracture'/'hinge' fracture, etc.
Callus formation	Yes or no If yes: weak, strong, exuberant
Periosteal reaction	Yes or no If yes: weak, strong, exuberant
Misalignment	Yes or no If yes: light, medium, severe
Pseudo-arthritis	Yes or no If yes: light, medium, severe
Degree and success of repair	Yes or No
Estimation of time elapsed since the trauma occurrence	Possible/not possible
Microscopic analysis	Yes or no
Special cases	Amputation/surgical interventions/prosthesis

Figure 3 Radiograph of right ribs with 'string of bead'. None of the ribs has fusion between them, despite the large calluses. The bones are illustrated before final processing. Their condition stimulated concerns that ribs 6–7, 8–9, and 11–12 may have been conjoined. Radiographs confirm no fusion (courtesy of Steve Symes).

Figure 4 A child of 2.5 months presented as an SIDS case, whose autopsy had diagnosed a shaken baby syndrome. The callus osseous observed in the posterior 8th left rib (first at autopsy and later in this RX), and a previous hospital internment when he was 1.5 months old, due to a bruise in the face consistent with a slap, both not explained by the parents, proved child abuse. A subdural hemorrhage and cerebral edema, in association with retinal hemorrhages, showed at histology not explained by the partum, helped in the diagnostic of the shaken baby syndrome.

recognized after new bone formation than in recent conditions, either by radiology or at autopsy. A discrepancy between autopsy and radiology may eventually occur. Apart from the callus formation, refracture of the existing calluses may be observed (Figure 5). The posterior fractures may be due to squeezing or shaking the child, while lateral fractures will be due to antero-posterior compression.

A difficult question arises occasionally when these rib (consolidated) fractures are argued to be resuscitation injuries. In fact, fractures by chest compression are very uncommon in child because of the elasticity of the immature ribcage. Moreover, if properly applied, chest compression in a child is done

Figure 5 The calluses are large and suggest numerous episodes of refracture (courtesy of Steve Symes).

with fingers and is unlikely to cause fractures. Normally, these fractures are observed in the anterior arch in the midclavicular line or sterno-condral junction, which is an important criterion for the differential diagnosis. However, the possibility of broken ribs in resuscitation situation should always be considered and diagnosed, carefully, on a case-by-case basis.

Fractures of the clavicle are relatively uncommon in children. However, those at the distal end may be caused by a sudden traction of the extremity. Fractures of the scapula (namely of the acromion) and sternum, although rare, can be related to child abuse, if other major trauma is excluded. Vertebrae, especially the lateral processes, should not be forgotten in an examination.

Wherever the site of the skeletal damage is observed, the characteristic pattern includes multiple traumas and variation in the age of the fractures. Accidental injuries usually produce single lesions, unless some bone disease, such as osteogenesis imperfecta (especially type V), infantile cortical hyperostosis, congenital syphilis, copper deficiency, or Menke's syndrome, can be proved.

In child abuse, bone damage must be related to any delay or absence of medical care, inconsistencies with developmental age, the history of injury changes over time, and to witness accounts.

Torture

Antemortem bone lesions may also be evidence of torture, as physical techniques are systematic or repetitive to force another person to yield information, to make confession, or for any other reason. However, in cases of torture, the antemortem lesions co-exist with recent perimortem fractures which would have probably caused the death of the victim. The issue will be to establish the right chronology of the injuries so that a reconstruction of the events may be possible. In order to achieve this objective, gross observations must be complemented by radiology and histological study. An excellent tool integrating the three perspectives (macroscopy, histology, and radiology) for the aging of fractures in human dry bones was published by Maat who compiled data from different sources

in a single table. The authors made a previous approach to this issue providing a table with the time needed for the normal consolidation of fractures of the totality of human bones. CT and other new imaging techniques will ensure the accuracy of diagnostics in the near future.

Reports of torture revealed that 10% of the injuries were fractures, in the following order: ribs, legs and pelvis, hands and wrists, spine, jaw, skull, and arms. Foreign bodies such as needles, wires, or wooden splinters can be found imbedded in the manual distal phalanges after fingernail torture. Compression of the fingers and toes can result from minor bone injuries or even the loss of hands, fingers, or digits. Cutting off parts of extremities will show in the examination because of the missing parts of the bones and the smoothing of the bone borders with some remodeling if the subject lived long enough. Whenever more than one adjacent bone is involved (for example, the metacarpals) fusion between the distal superior surfaces may occur. Consolidation of fractures of the forearm (ulna and/or radius) is typical of the defense of the prisoner trying to protect, intentionally or by reflex, his head. Fracture of the anatomical neck of the humerus and dislocation of the gleno-humeral joint may be observed in postural torture by suspension of the body by the wrists or the arms. The healing of the fractures mentioned above, apart from the callus formation, is traduced by thickening of the bones, which is sometimes exuberant in extreme cases where there is a lack of treatment; positional abnormalities due to the dislocations of bones and pseudoarthrosis that result from the nonfusion of the bones often occur without treatment. Infectious complications, such as osteomyelitis, can appear secondarily to soft-tissue lacerations or exposed fractures.

Ossified fractures of the toes, metatarsals, tarsals, the ankle, amputations of distal phalanges, as well as ligamentous injuries and flatfoot deformations can be observed in the technique known as *falanga* or *falaca*. This technique consists of beating the feet, mainly but not exclusively on the sole, to avoid the recognition of bruises in soft tissues. Thickening of the plantar aponeurosis (apparent in adipocere bodies) suggests previous torture. Consequently, the impairment of blood circulation and the necrosis of muscles can extend to the bones, leading to the necrosis of metatarsal and proximal phalanges. Fractures may then occur and form exostoses. *Palmatoria*, a unique method used in Guinea-Bissau, consisting of repetitive blows to the shin, create a periosteal thickening of the tibia apart from endosteal and intramedullary changes not visible in a classic examination (but seen radiologically) and can result in a fracture seen only in CT. Pellets and bullets may be found embedded in articulations, especially in the knees, a method known as kneecapping, which is also associated with fractures of the neighboring bones (legs and arms). The healing of these fractures, which may be splintered if high-velocity projectiles were used, is difficult and delayed; periostitis and osteomyelitis usually appear as complications. This method was used in North Ireland conflicts and also by American gangs that threaten to cripple the victim.

Healed fractures of the ribs and spine because of a beating in the thorax are common. Biomechanics of these fractures is complex and needs further research. Fractures by compression of the chest or pelvis are less known; they are difficult to interpret and occasionally are the object of undesirable speculation.

Although frequently mentioned in the literature, as a sign of manual or ligature strangulations, fracture of the hyoid bone seems to be very rare as a method of torture, because the time from torture to death is extremely narrow. Moreover, the real incidence of these fractures in all the compressions of the neck is much lower than previous reports in forensic textbooks which considered it as a classic sign of hanging or strangulation. In fact, case studies of fractures of the hyoid bone are scarce in the forensic anthropology literature.

A healing butterfly fracture of the mandible may be extremely useful to identify beating on the face and possible torture, such as by the butt or the barrel of a firearm. But in cases of peri-mortem fractures in this location, when the victim has been shot to the head, this is a typical fracture; although it is theoretically consistent with blunt trauma, it is an artifact of high-velocity projectiles (so-called Kolusayin fractures) and should be interpreted with caution. The healing stage of the fracture will be crucial to distinguish between a simple execution and previous torture before the execution.

Glossary

Anisotropic A characteristic of a material that has different mechanical properties when loaded in different directions due to its directional structure.

Bending (angulation) A mode of loading such that the bone bends around its axis and experiences tension on the convex surface and compression on the opposite concave surface.

Brittle Characteristic of a material that readily breaks without plastic deformation when subjected to stress.

Buttressing Areas of struts or thickening of the bone.

Compliance A measure of the ease with which bone deforms or the inverse of stiffness.

Compression A mode of loading where the forces are acting in opposite directions along the longitudinal axis of the bone. Compression results in a decrease in length and an increase in width.

Ductility The ability of a material to deform under tensile stress.

Elastic deformation Deformation or strain in bone that is reversible when the stress is released.

Elastic modulus (Young's modulus) The ratio of stress to strain in the elastic region of deformation. Because of the anisotropic nature of bone, the moduli in compression and tension differ in bone or the slope of the stress-strain curve.

Plastic deformation Permanent strain that is unrecoverable when the bone is unstressed. Plastic deformation occurs between the yield point and the failure point.

Remodeling The removal and replacement of bone at a particular location by the coupled action of osteoclasts (bone-destructing cells) and osteoblasts (bone-building cells).

Stiffness (rigidity) The ability of a material to resist deformation or the load required to cause bone to deform a given amount. It is measured as the slope of the stress-strain curve and influenced by the relative proportion of collagen and hydroxyapatite crystals.

Strain The dimensional change in loaded bone. The principal strains are normal or shear.

Strength The ability of bone to withstand permanent deformation (the load at the yield point) or fracture (the load at failure point).

Stress The load per unit area of a bone, measured in pascal (Pa). The stress can be normal or shear.

Tension A mode of loading in which the forces act in opposite directions along the longitudinal axis of the bone. Tension results in an increase in length and decrease in width.

Yield point The point where bone begins to deform plastically.

Introduction

Biomechanics is the science of mechanical laws applied to biological tissue. Trauma is an extrinsic agent, force, or mechanism that causes injury or shock to a living tissue, usually due to violence or accident. Hence, the biomechanics of bone trauma is the application of mechanical laws to describe and interpret bone trauma, and involves the examination of both the intrinsic (size, geometry, and material properties such as stiffness, elasticity, and density) and extrinsic (magnitude, duration, and direction of force) factors resulting in bone injury. Understanding the biomechanics of bone trauma allows forensic scientists to use the pattern of bone fractures to deduce the type and direction of loading that caused the bone to fail. This information then often can be used to determine proximate and ultimate cause of the injury.

Injuries to bone usually involve fracture (failure) or dislocation (displacement at a joint). The mechanisms of fractures are divided into direct, indirect, stress, or pathological. Fractures resulting from direct or indirect trauma are of greatest interest to forensic scientists. There are many direct and indirect agents that can cause trauma to bone including mechanical, thermal, electrical, and others. Most of the direct trauma of interest to forensic scientists results in injury at the point of impact due to blunt, sharp, or projectile forces. The differences

among these agents are primarily determined by the size of the impact area and the magnitude and duration of the force. Indirect trauma results in injury at locations other than the point of impact or applied force. Stress and pathological injuries are associated with repetitive forces or disease processes, respectively, that weaken bone. This article primarily focuses on fractures or disruptions in the structural continuity of the bone due to direct mechanical trauma.

Goals of Trauma Analysis

The goals of trauma analysis in a medicolegal situation are to determine the proximate (i.e., immediate mechanism) and ultimate (e.g., manner of death) causes of the trauma. This is necessary to aid in determining the cause and manner of death by the medical examiner. In skeletonized or badly decomposed bodies, traumatic injuries of the bone may provide a major avenue for determining the cause and manner of death. However, even in fresh bodies, the direct observation of hard tissue should be conducted in all areas of suspected trauma because the gross examination of bone can provide valuable information that cannot always be obtained using other tissues or other visualizing methods (e.g., radiographs).

While the goals of trauma analysis are to determine the mechanism and ultimate cause of the trauma, the first step of trauma analysis is adequate description of the injury, its location, and pattern. Unfortunately, there can be considerable variation in the expression of injury due to the same mechanism as well as similarities in injuries caused by different mechanisms. Proper description of the injury morphology (i.e., size, shape, location, line of fracture propagation, segment relationships, and pattern) is the basis for determining the mechanism and aids in interpreting the ultimate cause. Interpreting the ultimate cause of the injury requires additional information such as the pattern of trauma in populations, the context of the human remains, and other sources of evidence.

Bone Structure and Material Properties

To lay the foundation for how fractures occur, it is important to first have an understanding of the structure of the bone and its material properties. These principles guide the analysis of bone trauma and provide a framework for interpreting the proximate cause of trauma.

Bone Structure

The overall strength of the bone is dependent on its material composition, organization, and overall geometry (amount and overall distribution of the bone). At the most basic level, bone is a composite material composed of an organic matrix with embedded mineral crystals. The organic component consists of collagen and other noncollagen fibers, while the inorganic component is primarily hydroxyapatite crystals. The organic components of bone are primarily responsible for tension properties (i.e., elasticity and toughness), while the inorganic components are responsible for compression properties (i.e., stiffness). In addition to collagen and hydroxyapatite, living bone also contains several types of cells (i.e., osteoblasts, osteoclasts, and osteocytes), blood vessels, nerves, and a significant amount of water. The water in bone increases its resistance to fracturing by absorbing large amounts of energy. Bone generally exists in woven or lamellar form. Woven bone is unorganized and laid down quickly. It is typically found in fast-growing bones or in the callus produced during fracture repair. Lamellar bone is highly organized bone laid down in layers with the orientation of the collagen fibers at different angles in each layer. There are also two primary types of bone based on density and porosity that have different biomechanical properties. Trabecular bone (also known as cancellous or spongy bone), commonly found in the interior of a bone near the ends of long bones and in cuboidal, irregular, and flat bones, has high porosity, low density, and is organized as laminated struts called trabeculae. Cortical bone (also known as compact bone) is the dense bone that forms the thick outer wall of long bones and the thin cortex of cuboidal, irregular, and flat bones. Cortical bone is composed of lamellar bone interspersed with osteons that allow for the incorporation of blood vessels and bone maintenance cells. Osteons can either be primary osteons or secondary (Haversian systems) depending on whether they are formed new or formed by the resorption and replacement of existing bone in a process known as

remodeling. Cortical bone responds differently to loads depending on the number and size of osteons. Due to its structure, cortical bone is stronger along the longitudinal axis than along the transverse axis. Finally, the macrostructure of a bone is influenced by its cross-sectional shape, areas of buttressing (thickening), and differential density. During life, the architecture and material properties of a bone adapt to meet the functional demands it experiences.

Material Properties of a Bone

The strength of bone is generally defined as its ability to withstand loads (force or moment) without failing. Loads can be applied in tension (stretching), compression (compaction), bending (angulation), torsion (twisting), shear (sliding), or a combination of these basic components. These loads cause internal tensile, compressive, and shear stresses on the bone. The type of stress will vary with the direction of the force and the orientation of the bone. Bending loads produce tensile stress on one surface and compressive stress on the other, while torsion produces tension and compressive stress at an $\sim 45^\circ$ angle to the longitudinal axis and shear force in the transverse plane.

To understand how a bone behaves under loads, it is important to understand the relationship between stress and strain. Stress in its simplest definition is the intensity of load per unit area. Stress is generally measured on a small cube of bone to remove the effects of geometry. Strain, on the other hand, is the amount of dimensional change or deformation in shape that occurs due to an applied stress in one plane (Figure 1). Bone will fail when the strain becomes too great regardless of the level of stress. Strain can be either negative or positive depending on the type of load applied. For example, if the two ends of a cube of bone are pulled apart during tensile stress, the bone will undergo an increase in length (longitudinal strain) and a corresponding decrease in breadth (transverse strain). In this case, there is positive strain in length and negative strain in breadth. The ratio of transverse strain to the longitudinal strain is Poisson's ratio, which is ~ 0.3 for bone. If the load is applied in a manner that causes the angles of the bone cube sides to become distorted or slide, the bone is said to be undergoing shear strain.

Figure 1 Schematic illustration of normal (tension) strain and shear strain. Strain is the fractional change in dimension of loaded material. Normal strain along the longitudinal axis is the difference between the deformed length (y) and the original length (y_0) divided by the original length ($(y - y_0)/y_0$). The normal strain in the transverse axis is the deformed breadth (x) divided by the original breadth (x_0) divided by x_0 . Poisson's ratio is the ratio of the transverse strain (x) to the longitudinal strain (y).

Figure 2 Idealized schematic illustrating the principles of load-deformation and stress-strain curves. The ultimate force (or stress) is denoted by the height of the curve, while the ultimate deformation (or strain) is denoted by the point of failure. The area under the curve represents the work to failure. The area between the origin and the vertical line dropping from the yield point equals the amount of energy absorbed elastically. The area between the two vertical lines (yield and ultimate strain) represents the amount of energy absorbed plastically. The slope in the elastic region of the curve represents the modulus of elasticity or stiffness. The yield point represents the point when bone stops behaving elastically and begins to behave plastically.

To understand the relationship between stress and strain, imagine a cube of bone loaded in tension until it breaks. The load can be measured as a function of deformation to form a load-deformation curve (Figure 2). As bone is loaded, it will begin to deform. For a while, the deformation of bone is linearly proportional to the load placed on it. If the deformation is less than ~3%, the bone will return to its original shape once unloaded. However, as the load continues to the yield point, the curve begins to flatten. As can be seen in Figure 2, less loading is required to cause increasing deformation. If the load continues to increase, the bone will eventually reach a point of failure and will fracture. The load-deformation curve can be mathematically converted to a strain-stress curve to eliminate the effects of geometry. In the linear portion, the stress and strain are proportional to each other. The relationship of tensile stress to tensile strain is known as the modulus of elasticity or Young's modulus, while the ratio of shear stress to shear strain is known as the shear modulus. The greater the resistance of bone to stress (steepness of stress-strain curve slopes), the greater is its stiffness. If the bone is unloaded in the elastic region, the stress falls to zero when the strain returns to zero and the bone returns to its original shape. If the load is continued and deformation reaches the yield point, slippage occurs between layers of atoms and molecules at the cement lines, and the stress will return to zero but the strain will not. In this case, the bone is behaving plastically and will remain deformed without healing. If the load continues to increase, the bone will eventually reach its ultimate deformation or fracture point. Brittle bone will fracture under tension before or slightly after reaching the yield point and normally does not show any significant plastic deformation (Figure 3). Tough or ductile bone, on the other hand, will become plastically

Figure 3 Idealized schematic illustrating the principles of a load-deformation curve for different bone conditions and quality. Brittle bone is stiffer and therefore has a steeper slope but fractures with little or no deformation in the plastic region and requires less work for failure than normal bone. Ductile bone undergoes greater deformation before failing and requires greater work for failure than normal bone. YP, yield point; FP, fracture point.

deformed before breaking under tension. Brittle bone is more resistant to compression stress, while ductile bone is more resistant to tensile stress. The energy absorbed by a bone per volume of area is equivalent to the area under the stress-strain curve and is sometimes referred to as the modulus of toughness. The area under the elastic region is the amount of energy absorbed elastically, while the area under the plastic region is equivalent to the energy absorbed plastically.

The stress-strain curve provides a basic understanding of the intrinsic nature of how bone responds to mechanical loads, but it must be kept in mind that bone is a dynamic composite tissue that exhibits anisotropic and viscoelastic characteristics and has a unique geometry. During life, the mechanical characteristics of bone must combine to meet the need for a stiffness and compliance while minimizing skeletal weight. Stiffness of bone reduces strain so it does not deform significantly under load and allows muscles to function more efficiently. Compliance, on the other hand, allows bone to absorb energy and deform to avoid failure during direct or indirect dynamic loading from a fall or blow. The anisotropic nature of bone causes it to behave differently depending on the direction of the force. As a result, the strain on bone is not necessarily the same as the direction of the applied force. That is, the value of the modulus in the stress-strain curve can be different depending on the orientation of the bone. The viscoelastic nature suggests that bone can deform like an elastic material. However, like a viscous material, bone will continue to deform or creep under constant pressure and its stiffness depends on the rate at which the load is applied. Bone becomes more brittle under rapid loading. Therefore, the ultimate or fracture strain is decreased. Also, as a result of its viscoelastic properties, bone is nearly twice as resistant to failure in compression as in tension. This is why bone will normally fail under tension before compression in adults.

The actual forces required to break a living bone are frequently different from the intrinsic strength of bone material,

and numerous other factors can affect the force required to fracture a living bone. In a living person, bone is protected from fracturing through energy-absorbing mechanisms including muscle contractions and deformation of soft tissues. During a fall, for example, muscles contract and reduce the bending of bones by lessening the tensile forces, and soft tissue will absorb much of the energy. However, if the energy-absorbing mechanisms that protect the bone are impaired by surprise, restriction, or incapacity, bones are more likely to fracture under less force. The size and geometry of bones also affect their ability to resist fracture. The geometry of bones allows them to effectively withstand normal loads while remaining light. Intuitively, large bones distribute forces over a larger area and are therefore more resistant to fracture than smaller bones of similar shape. Bones with a larger cross-sectional second moment of inertia and polar moment of inertia are also more resistant to bending and torsional fracture, respectively. Bone that is further from the neutral axis is more efficient at resisting strain. If two bones have the same cortical thickness, the bone with the larger diameter will have greater resistance to fracturing.

Effects of Age and Disease on Bone Material Properties

The age of the individual and some diseases may affect the quality and geometry of the bone, and therefore can significantly influence the fracture risk. Bone's resistance to fracturing can be influenced by any process that changes its material composition and geometry. The ratio of inorganic and organic components of bone (bone mineral density, BMD) affects stiffness (Figure 3). Highly mineralized bone is stiff but also brittle. As a result, less energy is required to break brittle bone than more compliant, less mineralized bone (Figure 3). Immature bone has a lower BMD than adult bone. As a result, immature bones have greater elasticity but less stiffness than adult bones and can absorb more energy and deformation before fracturing. This is why children are less likely to experience bone fractures from trauma than adults. Incomplete fractures are more common in the immature skeleton because the bone undergoes large deformation due to the ductile properties of the bone (Figure 3). In older adults, on the other hand, the bones become more mineralized, making them stiffer and more brittle. As a result, the bones of older individuals are stronger under compression loads, but less energy is required to cause them to break under tension. In addition, the strength of bone in older individuals may be reduced because of the greater number of secondary osteons, reduction of water content, and the loss of bone, especially trabeculae. Secondary osteons reduce bone density and increase cement lines, while the loss of water decreases the amount of energy that can be absorbed from trauma.

Similar to age, pathological changes in bone can affect its quality and geometry. Individuals with diseases such as osteoporosis, osteogenesis imperfecta, osteomyelitis, diabetes, Paget's disease, Cushing's disease, rickets, scurvy, tumors, rheumatoid arthritis, and others may be at increased risk of bone fracture. Osteogenesis imperfecta, for example, reduces bone quality and causes long bone cortices to thin. Any apparent disease affecting bone should be noted and its role in the observed fractures should be discussed.

Fracture Propagation and Fracture Types

Fracture Propagation

When more energy is transferred to a bone than it can absorb, the bone will fracture because the strain will surpass the ultimate strain. Energy absorbed by a traumatic load builds up in the bone and is released by forming cracks. The greater the energy absorbed by the bone, the greater is the number of cracks that will form. As a result, high-energy trauma will cause bone to fragment, while low-energy loads will usually cause fracture without fragmentation. Bone is weakest in shear followed by tension and strongest in compression. Therefore, fractures will normally propagate in the bone along tension and shear planes. The shear planes run at $\sim 45^\circ$ angles from compressive and tensile stresses. Fractures also follow the path of least resistance. In the skull, for example, there are regions of buttressing (greater thickness) that impede horizontal bending of the skull bones. Therefore, fractures are more likely to occur between the areas of buttressing because the bone can be more easily bent. Fracture lines or cracks will often be diverted toward less buttressed areas. Likewise, fractures may be terminated at suture lines or preexisting cracks since the energy is more efficiently dissipated through these structures.

Fracture Types

The type of fracture produced in bone depends on the amount and location of force applied and the area of impact. Proper description of bone injuries can provide information regarding the type and direction of forces and aid in the mechanism and ultimate cause of trauma. Unfortunately there is very little standardization in the procedures or terminology for documenting bone injuries. Furthermore, most bone trauma classifications are derived from the medical literature that are not necessarily appropriate for forensic scientists. Bone fractures are commonly classified based on general fracture types that occur in all bones, fractures that occur in specific bones, and fractures that cause soft tissue damage. Detailed descriptions of fracture types for each major bones of the body can be found in many references (see section 'Further Reading'). The intent here is not to develop a standard system or provide an exhaustive list, but to give a biomechanical description of some of the fracture types commonly found in the forensic literature and typical forensic cases.

In all cases, bone injuries should be documented mentioning the bone or bones involved, specific location of injury on each bone, type of injury (fracture, dislocation, etc.), appearance of the injury, patterning of fracture lines, apparent direction of the force, length of the fractures, presence of deformation, evidence of the timing (antemortem, perimortem, postmortem) of the injury, and any evidence of complications. In addition, when possible, whether the fracture is open or closed, the percentage and direction of apposition (amount of contact between fragments in fresh or healed injuries), direction of rotation (internal or external rotation of the distal end), and degree and direction of angulation should be documented.

The first major distinction in fracture type is whether the break involves complete or incomplete discontinuity.

These two classes of fractures are then subdivided based on the type of force, pattern of cracking, degree of fracturing, and bone type. Incomplete fracture types are commonly described as bow injuries (the force is dissipated between the yield and failure points), torus, greenstick, toddler, vertical, and depression fractures. Complete fractures are classified based on their shape and location and include transverse, oblique, spiral, comminuted, butterfly, segmental, and epiphyseal fractures. Cranial fractures include linear (simple linear, diastatic, and stellate), crush (depressed), and penetrating. While discussions of the type of fracture are useful for understanding the mechanism of force, the different types of fractures are not mutually exclusive. Linear fractures, for example, may arise from a depression fracture associated with blunt trauma or from a penetrating fracture associated with gunshot projectile trauma. In general, the type of fracture that occurs is often associated with the velocity and mass of the striking object and the area of the impact forces.

General fracture types

Transverse fractures result from forces applied perpendicular to the longitudinal axis of the bone, often as the result of bending forces on brittle bones and bones that are not under compression due to weight-bearing functions. When bent, the tensile stress is applied to the convex surface opposite the direction of force and compression stress on the concave surface forming a neutral axis (point at which the tensile and compressive stresses cancel each other out) near the center of the bone shaft. Since bone is more resistant to compression than tensile stress, the bone will fail on the tensile side. As the fracture propagates across the shaft toward the compression side, the cross-sectional area of the bone is reduced and the neutral axis shifts toward the compressive side until the fracture is complete. If the bone is under compressive forces as well, a transverse fracture will begin on the tensile side, but as the fracture crack moves toward the compression side, shear forces become greater and the fracture will begin to travel along the shear plane at approximately a 45° angle in one or both directions because bone is weaker in shear than in compression. If the fracture is propagated in both directions, it will result in a butterfly fracture characterized by a wedge-shaped fragment of bone, with its apex on the tension side and base on the compression side. Whether a butterfly fragment is produced probably depends on the duration and magnitude of the bending and compression loads. Bending forces may result in an incomplete transverse fracture (beginning on the tensile side), called a greenstick fracture, that may or may not deviate at right angles. In greenstick fractures, the unfractured portion of the bone often remains permanently bent. Greenstick fractures are more common in immature bones that have greater compliance, but may also occur in adult bones such as the ribs. Under high loads, crushing or comminution of the bone may also occur. Avulsion fractures, which are usually of less forensic significance because they are self-inflicted, also result in a transverse fracture line. However, an avulsion fracture results when a muscle tendon, ligament, or joint capsule is pulled creating significant tensile stress that caused the bone to fracture.

Oblique fractures result from a combination of moderate bending and compressive forces or bending and torsion that cause the bone to break diagonally (often at a 45° angle) to the

long axis. The angle of an oblique fracture depends on whether the compressive or bending force is greatest. If the compression forces are greater, the fracture will be more oblique. If the bending forces are greater, the fracture will be more transverse. Long oblique fractures, which are often difficult to differentiate from spiral fractures, occur when the predominant force is torsion. Oblique fractures often begin as transverse fractures but quickly follow the shear plane, resulting in a break with a short transverse section and a longer oblique section.

Spiral fractures occur due to torsion or twisting force that produces a fracture that circles or spirals around the shaft. When a long bone shaft is twisted, the compressive and tensile stresses are at approximately a 45° angle to the shaft. Tensile stresses produce a fracture that winds around the surface and breaks completely when a longitudinal fissure occurs or the beginning and ending edges of the crack connect. The fracture originates where the tension stress is greatest and follows the angle of rotation until the fracture ends are approximately parallel or above one another. The direction of the twisting can be determined by the direction of the spiral.

Comminuted fractures are those that result in more than two fragments, and often result from large direct or indirect forces with high energy absorption. Indirect forces frequently result in a 'T' or 'Y' pattern fracture. Comminuted fractures may also result in direct blunt force trauma or penetration from a high-velocity projectile.

Crush fractures occur due to direct force to the bone which results in depression (forces originating on one side) or compression (forces originating on two sides) fractures. Depression fractures can result in incomplete penetration of projectiles or blunt trauma produced by an object striking the bone. The degree of fracturing is affected by the size of the impact area and the velocity of the force. If the area of impact is small and the velocity is great, the resulting fracture may be a penetrating injury.

Torus, buckling, or impact fractures are due to compression force and occur when the ends of a long bone are driven toward each other. The resulting fracture is an outward displacement of the cortical bone around the circumference of the bone, usually near the end of the long bone shaft. Examples of how this type of fracture occurs include fracturing of the proximal humerus when falling onto outstretched upper limbs or fracturing of the metacarpals when punching or striking an object with the fist. Because the diaphysis is composed of thicker, denser cortical bone and the metaphysis is primarily trabecular bone surrounded by a thin layer of cortical bone, compression forces are more likely to result in buckling of the metaphysis than of the diaphysis. Buckling is also more likely to occur in immature bones than in adult bones.

Cranial fractures

Fractures of the skull can occur from direct or indirect trauma. Linear, crush, and penetrating fractures are common with direct trauma. As with more general fracture types, these fractures are not mutually exclusive. Under direct trauma, the skull behaves similar to a semielastic ball. The curve of the cranial vault at the impact site will flatten or bend internally while the surrounding bone will bend outward. Fracturing will occur on the tensile side in areas of bending. Whether the fracture will begin at the impact site and radiate away or begin away from

the impact site and radiate in both directions probably depends on the elasticity of the skull, the size of the impact area, the size and shape of the object impacting the skull, the architecture of the skull at the impact area, the magnitude of the force, and other factors. Linear fractures often occur when the skull is struck or impacts an object of high mass. Low-velocity direct forces often result in linear or depressed (crush) fractures of the cranial vault. High-energy loads with a small impact area or pointed objects striking the skull will result in depression or penetrating injuries. Stellate or star-shaped fractures are formed by multiple linear fractures radiating from the point of impact. If the damage is more extensive, comminuted fractures may occur. Concentric fractures are produced when a blunt or penetrating object causes inward bending of the bone between radiating fractures. They generally circumscribe the impact area and are roughly perpendicular to the radiating fractures. As the plates of bone between radiating fractures bend inward, tensile stress occurs on the external surface of the outer table and progresses like transverse fractures from the outer to the inner table.

Bullet wounds are usually characterized by internally beveling entrance and externally beveling exit fractures. The shape of the wound depends on the angle at which the bullet strikes the bone. Because of the high energy and velocity associated with projectile force, the bone is unable to absorb the energy and fractures will commonly radiate from the initial perforating fracture. Concentric fracturing may also occur. However, unlike radiating and concentric fractures caused by blunt trauma, these fractures will initiate due to tension on the inner table of the vault due to intracranial pressure. In addition, trauma resulting from a gunshot will not display the inward deformation of the bone often seen in fractures occurring from blunt trauma.

Glossary

Blunt Any weapon, tool, or object that is smooth without any pointed or sharp part.

Compression mechanism (skull) Generalized pressure exerted on the skull, leading to irreversible deformation of the pieces of bones.

Compression side of the bone The concave side when the bone sustains a force that deforms it.

Elastic deformation Reversible deformation of the pieces of bones.

Plastic deformation Irreversible deformation of the pieces of bones.

Sharp Any weapon, tool, or object that displays a beveled (cutting or stabbing) part.

Tension side of the bone The convex side when the bone sustains a force that deforms it.

Introduction

Forensic anthropology deals with identification of skeletons or bones, but also analysis of the bone lesions in order to attempt to find out the cause and manner of death, each time it is possible. Forensic anthropology copes with skeletons discovered in a forensic context, but also with altered bodies (mutilation, cremains, decomposition) in which analysis of bone lesions will bring up significant information. Each time there is an important alteration of soft tissues as in autopsy cases of severe putrefaction, bones may show the signs of assault or of various processes altering the bones. On the other hand, some bones may be absent, due to human or animal activity. This can be a very important issue, especially for some specific locations, such as the hyoid bone and thyroid cartilage (the bone and cartilage of strangulation), ribs (bones of assault injuries, among others), and metacarpals and phalanges of the hands (bones of defense wounds, among others). Furthermore, bones may suffer from taphonomic alterations that may lead to difficulties in understanding the perimortem wound process.

Analysis of bone lesions needs a thorough methodology. The first step is to know if the bone lesion is of ante, peri, or postmortem origin. The second step is to classify the wound and assess the mechanism. In the third step, we may make some hypotheses on the tool that may have caused the bone lesion.

Ante-, Peri-, or Postmortem Origin of the Bone Lesion

This is a main issue, because most of the lesions are postmortem, and there is sometimes a great deal of controversy to ascertain a peri- or postmortem lesion, in front of courts. Briefly, *antemortem* lesions will be recognized when there is some healing of the bone, as a smoothing of the edges of the lesion, a production of bone around the lesion, an etched line parallel to and several millimeters from the actual fracture (periosteal uplifting). This needs 15 days (in average) of evolution in adults (sometimes as little as 7 days), and less in children. If the death occurs before this 13–15-day span of time, it is usually impossible to state the antemortem feature of the lesion.

Postmortem lesions are very frequent and of various origins. They are due to the weather or the soil, but also result from botanic, animal, or even human activity. Weathering cracks are very well known and may deeply alter the bone. Alternance of sun and rain, and cycles of freezing–thawing are examples that will alter the bone. The bone tends to lose its main properties with the span of time, that is, elasticity, hydration, and stiffness. Therefore, dry bones (loss of collagen and water) will react differently in comparison with green bones. Unfortunately, green bone (at the time of death) becomes a dry bone after a span of time that differs from one case to another, because it is dramatically linked to the environment of the bone. It is usually impossible to differentiate between a postmortem fracture that occurred on a (still) green bone and a perimortem fracture. The hallmark of a postmortem fracture is probably the discoloration of the edges of the lesion. Unfortunately, this sign can be useful only when present, which demands probably months or even years to be clearly visible.

Eventually, *perimortem* lesions are very difficult to state with certainty. The issue comes from a period of uncertainty, as the antemortem lesion cannot be claimed (less than about 13 days between the lesion and the occurrence of death), and the postmortem lesion as well (when the fracture or lesion occurs onto a green bone, and when there is no discoloration of the edges of the lesion). Greenstick fractures, joined skull fractures (the fragments are not totally separated along the margin of the lesion), depressed skull fractures, concentric and radiating fractures, and stellate fractures are observed in green (elastic) bones and therefore are usually of perimortem origin. As mentioned, the gradual loss of elasticity and water of the bone will lead to a brittle bone. The bone tends to shatter into smaller fragments. These differences may be difficult to ascertain, and, to tell the truth, the main hallmark of a perimortem fracture is when it is due to a sharp force injury, or a gunshot wound. These kinds of mechanisms are nearly always of perimortem origin. It is quite unusual that a gunshot wound occurred postmortem, and sharp force injuries as well. Chopping (blunt–sharp) and above all blunt trauma raise more uncertainty. We have dealt with several skeletons where a blunt or even sharp–blunt trauma was due to the fall of a rock on the skeletonized body.

Biomechanics

There are theoretically three subsequent phases when a bone sustains stress: (i) *Elastic phase*. In the beginning the load is relatively light and the bone will deform but this deformation is reversible: the bone is able to come back to its original shape (elastic deformation) as soon as the stress stops. In this first phase, the strain (the deformation) is proportional, in response, to the stress (the load); (ii) *Plastic phase*. If the load is more important, the bone enters into a plastic deformation phase. After deforming in response to the stress, it is unable to come back to its original shape as the stress stops: there will be a permanent (plastic) deformation. During this phase, the stress-strain curve is not straight, because there is no proportionality any more between stress and strain; (iii) *Fracture phase*. If the load is more important and exceeds the elastic and plastic components, the bone fractures.

Furthermore, we have to keep in mind that bone is a visco-elastic material, and is therefore twice stronger in compression than in tension. Thus, angulation of the bone will increase tensile forces on the convex side and compressive forces on the concave side. The bone will always yield first on the side of tension. The fracture begins under tension, keeps on toward the compression side, becoming more angulated, according to the shear forces that are generated. More about this is discussed elsewhere in this encyclopedia.

Classification of the Bone Lesions

Generally speaking, there are five kinds of lesions encountered in forensic anthropology: sharp force injuries, blunt force injuries, chopping wounds (blunt-sharp (if the blunt mechanism is predominant) or sharp-blunt (if the sharp mechanism is predominant) force injuries), gunshot wounds, and carbonization. An instrument is qualified as *sharp* when it presents a beveled part. It is very often a metal blade (e.g., a knife) which will act by cutting (when the blade moves more or less in the direction of the bone) or stabbing (when the tip of the blade acts perpendicularly or obliquely against the bone). But any beveled area of any instrument or element belonging to the environment may act like a blade or tip, under the condition that this part is beveled. The sharper the beveling, the easier the instrument will cut or stab. A *blunt* instrument is smooth, without sharp or pointed areas. An example of a blunt instrument is a bludgeon. The blunt instrument gives a pressure when it strikes the bone. The *sharp-blunt* or *blunt-sharp* instrument displays a sharp area, but also acts as a blunt tool, usually in reference to its weight or the violence of the blow (therefore, its kinetic energy). Thus, the blunt or sharp action is only a mechanism, and the element that has been able to produce it may be a weapon, a tool, an object, or any element of the environment. The main point is that the blunt element will lead to a blunt trauma, the sharp element will lead to a sharp trauma (a cutting or stabbing lesion), and the blunt-sharp element will lead to a blunt-sharp lesion, mixing both mechanisms. An axe is a good example of a sharp-blunt instrument, which acts by the sharp part of the blade, but also creates a blunt

mechanism according to the weight of the instrument. Eventually, we will deal with the main aspects of the *gunshot wounds* to the bone. In this short article, we will preclude carbonization of the bodies and the study of burned bones.

Sharp Injuries

Any sharp instrument will penetrate very easily into the bone, without any pressure exerted on it. The consequence is a very clear lesion, with regular edges of the wound. *Cutting* is due to the moving of the beveled area, for example, the blade of a knife, more or less in a parallel direction to the bone. The result is a linear or arciform (curved) lesion, often of small size. The arciform shape is explained by the displacement of the perpetrator or the victim during the cutting. This cutting lesion may be particularly seen on some specific locations of the body: the hands, the ribs. Concerning the hands, it is of paramount importance to examine all the metacarpals and phalanges very carefully. These kinds of lesions are very frequent in sharp assaults, and are called defense wounds. When there is an assault with a knife, the tendency of the victim is to protect himself or herself by putting the hand in front of the head. That is the reason why defense wounds are very frequent in this kind of foul play. Concerning the ribs, all 24 ribs (if available) must be examined with a great deal of attention. A cutting wound of an edge of a rib will be often of very small size, sometimes tiny, but of great importance. Occasionally there is a 'mirror lesion,' concerning two adjacent ribs. This double-sharp lesion occurs when the double blade penetrates between two adjacent ribs, leading to a cutting mark on both edges, or a cutting mark on one edge and a shaving pattern of the other edge. If it is a single blade, there is a sharp cutting wound on one rib, and a more or less blunt wound (chipping, irregular edges of the lesion) on the adjacent rib.

Stabbing is due to the percussion of the tip of the blade perpendicularly or obliquely to the surface of the bone. It may release a tiny mark on the bone or perforate it, passing through the bone. These stabbing wounds are usually seen on the sternum, scapula, ribs, skull, and sometimes on the long bones. Occasionally, the tip of the blade breaks and remains embedded within the bone.

The blade may penetrate through the thorax, giving a cutting lesion on one edge of the rib (and sometimes a mirror image) and then the blade moves on to the vertebra, giving a stabbing lesion on this last bone. Thus, two wounds may correspond to only one strike.

Stabbing wounds are sharp force injuries, and are typically very clear (clear shape, clear edges). But it is quite frequent that the perpetrator or the victim or the blade moved during the assault, so that some pressure is exerted to the bone, leading to some chipping of the lesion. Scanning electron microscopy has showed that the tip very often gives some pressure on the bone, especially when there is a tilt, and raises one side of the bone.

Blunt Injuries

Skull lesions

The methodology of analysis needs the study of three features: (a) the point of impact, (b) the associated fractures, and (c) the signs of compression.

Point of impact

A localized trauma leads to a localized deformation. Due to the elastic property of bones, the bone may return to its original shape. Therefore, the point of impact may be absent, and this is not a rare situation. A blow with a bludgeon is a good example of this possibility. The instrument is really blunt, and if the blow is not too violent, the deformation at the point of impact will be reversible, and there will be no visible lesion at the area of impact.

Sometimes the blow results in bone ecchymosis. This lesion does not display any sign on the external or internal table of the skull, but fine fractures and bleeding of the trabeculae of the diploe occur and explain the lesion. These bone ecchymoses have been described in old forensic literature when the diagnosis was made by transillumination (i.e., observing the skull through a source of light to see nonphysiologic discolorations of the skull) and by histopathology. More recently, bone ecchymoses have been confirmed by magnetic resonance imaging (MRI).

When the blow is more violent, there may be an indented fracture at the point of impact. The instrument produces an (incomplete) lesion of penetration or a (complete) perforation of the skull. In the case of a blunt instrument, as it cannot penetrate the bone because of its smooth shape, it will exert a lot of pressure on the bone. Therefore the point of impact, when it exists, will be unclear (the shape is vague and the edges are irregular).

Fractures

Fractures correspond to the dispersion of kinetic energy. They may be absent because the kinetic energy has been totally absorbed by the elastic deformation of the skull at the point of impact or by the indented lesion, when present. Fractures may be present, with or without any visible lesion at the point of impact.

Radiating or even concentric fractures may appear around the point of impact, which may be observable or not. The dispersion fractures of the skull vault are quite common. When they are caused by a blunt and quite light instrument, like a bludgeon, and if the blow is not too violent, fractures may be visible without any point of impact. The same pattern is observed when the victim falls from his or her height on the flat ground: fractures of dispersion are observed, without any point of impact. According to some authors, the fractures do not always appear at the point of impact, this phenomenon being explained by the transmission of the forces at a distance but this statement is a source of controversy.

The fractures of the base of the skull are frequent and potentially very dangerous. They occur from impacts on the skull, the face, the mandible, or by compression. One can distinguish between (a) longitudinal fractures of the base, usually due to an impact on the front or on the back of the head and (b) transverse fractures of the base, which are usually due to lateral impacts of the vault. A quite common fracture is seen along the two petrous bones, and is usually considered to be due to a lateral impact (but it is not always the case). Hinge fractures are transverse fractures that walk in front of the petrous bone through the sella turcica, and are usually linked to lateral impacts to the head.

Compression of the skull

Compression of the skull is due to a generalized (and not a localized) pressure on the skull. The skull will decrease its size in the direction of the compression. On the first occasion, an elastic (and then reversible) deformation of the skull is observed; then a plastic (and then irreversible) deformation occurs, and the fractures appear in the direction of the force.

Compression is stated when there is a widening of the sutures and above all a widening of the fractures (termed 'diastatic fractures'). This widening is explained by the permanent deformation of the pieces of bones which cannot perfectly come back to their original shape. The compression is seen when a 'static loading' is applied to the skull. Theoretically, it rules out a high-speed projectile. It may occur with a slow-speed projectile and, above all, with a blunt trauma, where the stress is particularly slow.

The mechanism of compression is frequent in forensic pathology and anthropology: head rolled over by a vehicle, violent blow to the head, particularly when it is blocked against a wall or the ground, impact on the vertex of the head, fall from one's own height with head impact against the ground, fall from a height on the feet. All these situations tend to decrease the size of the skull in the direction of the force. To be sure, the fall from some height on the vertex leads to a very significant compression of the skull, with numerous and wide skull fractures, and a significant plastic deformation of the pieces of bone.

Ring fractures are very peculiar, occurring around the foramen magnum, sketching a ring pattern, associated with a diastasis (widening) of the mastoid suture and fissures of the petrous bone; they are usually attributed to a downward compression of the skull against the vertebral column (fall from a height on one's feet, violent vertical blow on the vertex), or a violent upward vertical blow on the chin (uppercut) or occiput. According to some authors, the downward force to the occiput should result in an internally directed beveling, while an upward force to the occiput should result in an externally directed beveling.

Chopping Injuries

In chopping wounds, both mechanisms (sharp and blunt) are associated with the injury. Thorough observation of the point of impact is required: it may be absent; if present, we have to observe the shape (clear or blurred) and the edges (clean or irregular). The presence or absence of dispersion fractures, and the presence or absence of signs of compression, are indispensable clues. This three-step analysis allows for the clear diagnosis of the mechanism. The sharper the instrument, the easier is the penetration, the less deformation exists at the point of impact, the less local pressure is exerted, and then the clearer is the shape of the impact lesion, the more regular are the edges of the lesion, and the less fractures of dispersion are observed. Conversely, when there is a violent blunt trauma, the instrument tries (but cannot) penetrate the skull, and therefore the lesion at the point of impact is unclear, the edges are irregular, and there are numerous associated fractures. As an example, with a blunt trauma by a hammer (Figure 1), the area of impact is unclear, and there are often

Figure 1 Blunt trauma with a hammer. The point of impact is very unclear ('ghostly' appearance, wide arrow). There are dispersion fractures (thin arrows) and compression mechanism as well (very thin arrows), with significant widening of the edges of the fractures.

Figure 2 Sharp trauma with a sharp, pointed pick. The point of impact is very clear, with clean and regular edges. There is no associated fracture. Small irregularities of the edges are visible, only with some magnification, demonstrating some pressure exerted while perforating the skull.

impressive associated dispersion fractures. This can be explained by the huge pressure that is exerted onto the skull at the point of impact. Conversely, with a stabbing wound with a sharp pick (**Figure 2**), the perforation is very clear, the edges of the wound are very regular, and there are no associated fractures. In chopping (sharp-blunt) wounds, for example with an axe, a hatchet (**Figure 3**), or a machete, the lesion mixes both features (blunt and sharp). Very often, the weight of the weapon, and the violence of the blow explain the blunt component of the lesion (irregularities of the edges of the lesion and associated fractures). A wound due to an axe will show a straight regular edge with beveling and a blunt second edge with chipping off of bones and associated fractures of dispersion. Eventually, compression (**Figures 1** and **4**) is due to a generalized pressure exerted to the skull and leads to several or multiple wide fractures with permanent deformation of the pieces of bones. Compression may occur with blunt or blunt-sharp instruments.

Figure 3 'Sharp-blunt' trauma by a hatchet (chopping wound). There is an irregular edge (wide arrow) and fractures (thin arrows), which represent the blunt part of the injury. The middle arrow points to a regular, beveled edge, which represents the sharp part of the injury.

Long Bones

Sharp trauma of long bones is unusual, except in cases of postmortem dismemberment of the body. In this last case, the bones are of great value, showing specific injuries linked to the blade of a knife (sharp injury), the using of an axe or hatchet (sharp-blunt injury), and the using of a saw, which releases very valuable saw marks depending upon the type of saw. Basically, there are hand-powered saws and mechanical saws. The main features of a saw are the teeth per inch or points per inch, and the presence of an alternating, racker, or wavy set. The clues left by a saw include the false start kerf (initial corners, kerf floor, floor corners) and the bone cross section (initial corners of the kerf, kerf walls, breakaway spur, and notch). We will not insist on the saw marks analysis and further information may be found in reference readings.

Except for dismembering, sharp wounds of long bones share the same features as the other locations (cutting or stabbing injuries). Chopping wounds of long bones are possible, for example, through an assault with an axe or a machete, leading to a sharp-blunt injury, as described earlier.

There are numerous basic mechanisms of blunt trauma of the long bones. Alms proposed to distinguish between (i) *traction* (leading to a transverse fracture); (ii) *axial compression* (leading to an oblique fracture); (iii) *bending* (leading to a transverse fracture); (iv) *bending under axial compression* (leading to an oblique transverse fracture). The more the axial compression, the more vertical is the oblique part of the fracture. A butterfly fragment is often seen on the side of compression. This butterfly fragment is of great value, because it indicates without any ambiguity the side of tension and the side of compression, and therefore gives the direction of the blow; (v) *twisting* (leading to a spiral fracture); (vi) *twisting associated with axial loading*; in real life, twisting is associated with axial loading. The more the axial compression force, the

Figure 4 Compression mechanism. The fracture displays a widening (arrow) of its two edges. This is usually termed 'diastatic fracture' and indicates an irreversible plastic deformation of the pieces of bones.

more nearly vertical is the plane of shear forces; and (vii) *twisting with bending*; this mechanism looks like an angulation about an oblique axis. Usually this kind of fracture occurs at the junction between the middle and lower thirds of the tibia.

In short, transverse fractures result from angulation, oblique transverse fractures from an angulation with axial loading, spiral fractures from an axial twist with or without axial loading (the more the axial loading, the more vertical is the spiral), butterfly fractures from bending with axial loading, and oblique fractures from axial loading.

For the forensic assessment of the bone, a very important clue is the 'direct' or 'indirect' feature of the traumatism. Direct blows on the bone will lead to an angulation and therefore to transversal fractures. If both bones of the forearm are concerned, the fracture is at the same level on the two bones. If the blow strikes the inferior limb, there is very often an axial loading at the time of the blow (the inferior limb bearing the weight of the body), so that the fracture is often oblique transverse. In a forensic context, a transverse fracture of the superior limb and a transverse or oblique transverse fracture of the inferior limb may be possibly linked to an assault, with a direct impact on the forearm or the leg with a stick, for example. Conversely, spiral fractures of the limbs are in favor of a twist of the shaft, and then possibly an accident. A transverse fracture of the tibia with a butterfly fragment may be explained by a bending of the bone; therefore, it may be an accidental strike of the inferior limb by a car. For little children, spiral fractures may be due to child abuse with a violent torsion of the superior or inferior limb.

Other Locations

Blunt or sharp injuries of the *forearms* and *hands* are often defense wounds. That is the reason why the little bones of the hands are so important in forensic anthropology and have to be properly and thoroughly collected at the crime scene. Very often these lesions are tiny, and the bones must

be well prepared to be sure that there is no sharp lesion. Occasionally, suicide by phlebotomy with a blade used on the wrists may concern the forearm bones.

Blunt trauma of the *ribs* is frequent in cases of assaults or falls. Sharp injuries of ribs are of paramount importance. They are usually of small size (a simple tiny nick), and justify a serious preparation of the bone. It is impossible to see them if the ribs are not perfectly clean.

Blunt *facial injuries* by weapons like sticks or even fists are frequent and lead to anterior teeth fractures, nasal and zygomatic fractures, and blowout fracture of the orbit. The latter is seen when the eyeball is forced against the fragile orbital plate.

Hyoid bone, *cricoid*, and *thyroid cartilages* may show fracture or dislocation, resulting from strangulation. This is not always the case, because young victims display an important elasticity of the hyoid bone or thyroid cartilage, so that there is often no fracture, though strangulation really took place. Ossification increases with aging and leads to easier fractures by strangulation. Hanging leads to fractures or dislocations of the horns of the hyoid bone, and the horns of the thyroid cartilage, but these fractures or dislocations are not compulsory.

Gunshot Wounds

Gunshot wounds cause peculiar blunt trauma due to projectiles shot by a firearm. The peculiarities come essentially from the velocity of the projectile, in comparison with a blunt trauma, which is very low in comparison, even if the blow is very violent. Analysis of gunshot wounds to bones needs to underline the entrance, the exit (when present), the direction of the shot, and the distance of the shot. We will only deal with gunshot wounds to the skull in this short article.

Entrance Gunshot Wounds

The main features of a typical gunshot entrance wound to the skull are the circular or oval shape, the regularity, with sharp edges, a clear punched-out external appearance, and the *internal beveling* of the wound, that is, the opening is beveled in the direction of the shot (Figure 5). This can be symbolized by a speaking tube (Figure 6), the widening of the tube indicating the direction of the bullet. This last feature is really the hallmark of the bony entrance wound, but may be partial (only a part of the circumference displays some beveling), very tiny (and difficult to assess) or even absent (especially when the bone is very thin, like in the orbital walls). When present, internal beveling is very useful (Figure 5), especially when the opening displays unusual shapes, is irregular, is (occasionally) larger than the exit wound, or when the skull is fragmented. The explanations of internal beveling are quite unclear, but the pressure exerted by the bullet to the bone in the direction of and laterally to the pathway is probably a good explanation. It has to be pointed out that, though beveling is considered as the hallmark of gunshot injuries, it may exist with other kinds (e.g., sharp-blunt instruments) of perforations of the skull. It is said that the constitution of the skull vault with two layers of compact bone, separated by a layer of cancellous bone (the diploe), gives part of the explanation of the

Figure 5 Typical skull entrance gunshot wound. The perforation is round, quite regular (though there is some chipping of the edge of the hole), and without beveling on the exocranial vault (left). Conversely, there is an obvious beveling of the same wound on the endocranial vault (right). The direction of the bullet is obvious from the outside to the inside of the skull.

Figure 6 This sketch emphasizes the direction of the bullet, that is, the enlargement of the perforation (beveling), like a speaking tube. Sketch by Benjamin Maes.

internal beveling of an entrance wound. But beveling in the direction of the shot does exist with other locations, like the edge of a long bone.

As for gunshot wounds to the skin, there can be very *atypical cases of gunshot entrance wounds* to bones. The shape may be triangular, rectangular, or irregular. These variable shapes may gain some explanation from several factors, as the yawing and tumbling of the bullet, its deformation against the bone, the slight width of the bone wall, or the presence of intermediate targets. Occasionally, the bullet digs a tunnel within the bone. This is rare because the high pressure associated with the pathway usually leads to a burst of the bone. But tunneling may be observed with small calibers, for example, in ribs or vertebrae.

External beveling of an entrance wound is very rare, usually involving handgun contact wounds, and must be differentiated from chipping off of the edges of the opening, the latter being very plain. Usually, a more or less typical internal beveling is associated with the external beveling. Explanations of this inverted beveling of entrance wounds include the forceful

return of gases in a contact shot and the blowback from pressure associated with temporary cavity formation. The twisting of the bullet while perforating the skull has been presented as an explanation, but must be ruled out because the twisting rifling is very slow in comparison with the velocity of the bullet.

Occasionally, as entry wounds to the skin, the bony entrance is larger than the exit wound. This phenomenon is well known, and is usually dedicated to peculiar missiles like Brennekes.

Some gunshot entrance wounds may look like a blunt or a sharp-blunt (stabbing-blunt instrument) trauma. This may be explained by the fact that the bullet is blunt, but its tip may act as a pointed object, due to its velocity, especially when the bullet displays a pointed nose (and not a blunt nose or a wadcutter), when the bullet strikes perpendicularly to the bone, and when it is not destabilized before striking. Comparison of blunt trauma and gunshot trauma fractures show that plates of bone due to radiating fractures of the vault are levered out in gunshot wounds (the converse in blunt trauma). Concentric fractures will start under tension (in the inner table) and progress to the outer table, so that concentric fractures are beveled externally in gunshot wounds (the converse with blunt trauma).

But, most of all, shattering and fragmentation of the bone may lead to difficulties. In the context of forensic anthropology, it is not rare that some parts of bones are missing or destroyed. A semilunar defect must always draw attention and a gunshot wound must be suspected. The discovery of an internal beveling and the association with radiating or concentric fractures may help the diagnosis of a bullet perforation. x-Rays may release some clues, when little particles of metallic density exist along the edges of a defect. Sometimes the presence of radiating or concentric fractures without any hole (missing or destroyed) allows for the suspicion of a gunshot wound.

A serious pitfall occurs when the bullet enters through a natural hole, like the foramen magnum, or the orbits (the orbit walls are often destroyed in a forensic anthropological context). In these cases, there is no visible skull entrance.

Exit Gunshot Wounds

Exit wounds are usually irregular, larger in size than the entrance, and also display an inward clean punched-out appearance and an external beveling (in the direction of the bullet). The increase in the size ratio is slight to very significant (ranging from 1.14 to 5.76 times in a series of 17 entrance per exit wounds). The explanation of the size increase is the instability (tumbling, loss of gyroscopic twisting) and the deformation of the projectile. This was stated by experimental studies of skin gunshot wounds in animals with nondeformable spheres as missiles. The shape of the exit wound is usually round or oval, but may also display a square, a rectangle, or a triangle shape. Often the shape is more irregular than the entrance wound. To be sure, an exit wound may be absent if the bullet has stayed inside the brain. As for the entrance, the bullet may also exit through a natural hole; in this situation, there is an entrance, but no exit and no bullet.

Again, external beveling is a hallmark of the exit wound, but, as for entrance wounds, may be partial, slight, or even absent, especially in thin bones. Internal beveling of an exit wound seems to be a very rare situation.

Fractures

Though fractures associated with gunshot entries and exits are really frequent, they are not compulsory. The perforation by the bullet is the primary fracture, the radiating fractures are the secondary fractures, and the concentric fractures are the tertiary fractures. Theoretically, concentric fractures occur if the kinetic energy is not dissipated by the hole and the radiating fractures. It has to be pointed out that the fractures of the entrance walk faster than the bullet, so that the fractures coming from the exit wound are stopped by the fractures coming from the entrance wound (crossing rule, also called Puppe's rule). (Puppe was German and he described his crossing rule in the German language as early as 1914, and was further quoted by Madea and Staak). This may be of interest in order to state the area of the entrance and exit wounds when the skull is fragmented. This rule is also valuable when there are multiple shootings. The occurrence of fractures depends upon several factors, including the kinetic energy, the intrinsic behavior of the bullet (mushrooming, fragmentation), the destabilization of the bullet, the thinness or thickness of the bone, and the presence of an intermediate target.

Direction of the Shooting

In forensic cases, it is essential to give the direction of the shooting. The first assessment is to state the exact location of the entrance and exit wounds (when there is an exit wound). The features described earlier usually allow for this assessment. Then the direction of the shooting is straight between both holes. The angles have to be determined in reference to the horizontal, sagittal, and coronal planes; for the skull, the horizontal plane is the Frankfurt plane.

If there is no exit, the direction is stated between the entrance and a contralateral impact, when it exists (e.g., a bone ecchymosis or a little shattering of the inner table of the skull). Occasionally, the bullet or a fragment of it may be embedded inside the bone, and x-rays are of great value in these cases. If any of these signs is absent, one has to try to assess the direction of the bullet by observing the entrance hole: theoretically, if the hole is round, the bullet has struck perpendicularly to the bone; if the hole is oval, the bullet has struck with a tilt; and tangential wounds are very peculiar. Furthermore, it is said that beveling is elongated in the direction of shooting, but unfortunately this is not always the case.

Ricochet inside the skull is possible, but only occurs with small calibers when the bullet has lost nearly all of its kinetic energy. The deviation of the bullet after striking a bone is possible for the same reasons. Occasionally, the bullet has sufficient velocity to perforate a big vessel, and then is carried away in the blood circulation (this is termed 'bullet embolus, embolization, or embolism'). It is said that a low kinetic energy bullet may pass around the skull under the scalp, or around the thorax under the skin. We have never observed these last two situations.

Range of Shooting

Range of shooting is of paramount importance to reconstruct the death scene. Generally speaking, the intensity of fractures depends (among other factors) on the kinetic energy and then in part on the distance of shooting. High-speed projectiles produce multiple and intense fractures. But contact handgun shots, and above all contact shotgun shots, produce severe fractures often with bone loss and opening of the sutures. This is well explained by the massive increase of pressure inside the skull, due to gas entering from the weapon.

Caliber of the Bullet

The size of the defect does not reflect the size of the bullet. The intrinsic features of the bullet (shape, strength), the behavior of the bullet (tumbling, mushrooming, instability), and the intrinsic features of the bone (thickness, brittleness) are able to change the dimension of the hole.

Tangential Gunshot Wounds

Tangential gunshot wounds must be well known. Semilunar defects, grooves, gutter wounds, and keyhole defects have been described.

Semilunar defects are seen when the projectile strikes the very edge of a bone. It may be the edge of the orbit, the zygomatic process, a long bone, and even a vertebral plate, a rib, and so on, in fact, any bone whose edge is struck tangentially. The main feature of this tangential lesion is the presence of a beveling in the direction of shooting. Usually, this beveling is obvious in thick bones (like the edge of a femur or a humerus) but can be difficult to assess in thinner or slighter bones (e.g., ribs) that tend to burst.

Grooves may be dug up within bones, like the horizontal ramus of the mandible. We have also seen this kind of lesion in a strong mastoid. The bone must be strong enough, and the shooting really tangential, so that the bone can support the track of the bullet without bursting.

LaGarde in the early twentieth century described *gutter wounds* to the skull. Three degrees were recognized by this author. In the first degree, only the outer table was fractured. In the second degree, the outer and the inner table were fractured (the latter by the waves of pressure). In the third degree, there was an actual perforation of the outer table, the diploe, and the inner table as well. Nevertheless, all these gutter wounds are tangential, according to the fact that the bullet strikes the skull but does not enter the braincase. The bullet will or will not keep the same angle (ricochet if the angle differs after having struck the skull). Even if the bullet does not penetrate the skull in these cases, the skull trauma is obvious and may lead to serious complications and even death, with or without fragments of bones penetrating the brain.

Keyhole defects have been described with handguns and shotguns as well. The bullet strikes the skull tangentially, and then is fragmented. One of the two fragments enters the skull, giving a circular or oval defect with internal beveling that represents the initial impact and the entrance. And the other fragment immediately exits, creating an exit wound with external beveling, often more irregular than the entrance.

Figure 7 This sketch underlines a typical keyhole lesion. The bullet has struck the skull tangentially and has split. One of the two fragments penetrates the skull (no beveling on the exocranial vault, and we can guess that there is some internal beveling at the top right of the perforation). The second fragment exits immediately, creating an exit with external beveling. The entrance and exit are contiguous on the bone. Sketch by Benjamin Maes.

Occasionally, the bullet does not split and no fragment enters the skull. The keyhole pattern (**Figure 7**) has to be well known by forensic pathologists and anthropologists, otherwise it is a great source of confusion. In forensic pathology, there are often two noncontiguous superficial holes in the skin, due to the bullet entering and immediately exiting. But in bone, the two holes are contiguous and termed keyhole defect or keyhole lesion. Keyhole defects of an exit wound are also reported on, but appear to be definitely exceptional.

Glossary

Comparison analysis Comparison of the features of a person shown on a reference image with the features of a suspect shown on a comparison image.

Comparison photo Photo showing a suspect in the same perspective as the perpetrator on surveillance material.

Feature analysis Analysis and description of individual features of a person shown on a reference image.

Reference photo or video Photo or video recorded by a surveillance camera showing the perpetrator.

Abbreviations

Alare (al)	The most lateral point on each alar contour
Cheilion (ch)	The point located at each labial commissure
Endocanthion (en)	The point at the inner commissure of the eye fissure. The soft endocanthion is located lateral to the bony landmark that is used in cephalometry
Exocanthion (ex)	The point at the outer commissure of the eye fissure. The soft exocanthion is slightly medial to the bony exocanthion
Gnathion (gn)	The lowest median landmark on the lower border of the mandible. It is identified by palpation and is identical to the bony gnathion
Gonion (go)	The most lateral point of the jawline at the mandibular angle
Postaureale (pa)	The most posterior point on the free margin of the ear
Preaureale (pra)	The most anterior point of the ear, located just in front of the helix attachment to the head

Pronasale (prn)	The furthest protruding point of the apex nasi, identified in a lateral view of the head in the rest position
Pupil (p)	Determined when the head is in the rest position and the eye is looking straight ahead
Sellion (se)	The deepest landmark located at the bottom of the nasofrontal angle
Stomion (sto)	The point at the intersection of the MSP with the horizontal labial fissure between gently closed lips, with teeth shut in the natural position
Subaureale (sba)	The lowest point on the free margin of the earlobe
Subnasale (sn)	The midpoint of the angle at the columellar base where the lower border of the nasal septum and the surface of the upper lip meet
Superaureale (sa)	The highest point on the free margin of the auricle
Tragion (t)	The notch on the upper margin of the tragus
Trichion (tr)	The point on the hairline (if present) in the MSP
Zygion (zy)	The most lateral point of the cheek region

Introduction

The study of recognition and identification processes probably has to do more with the cognitive sciences; however, in the forensic scenario, it is frequently necessary to identify people according to their somatic traits. In theory, each person can be distinguished from all others according to appearance. For this, the features must be closely examined. In daily life, one is sometimes mistaken by confusing a person with somebody else, but the actual existence of a real 'look-alike' who displays the exact combination of features has not been scientifically proven. In fact, differences in certain features that are not noticed with a fleeting glance or when the person is not really well known to us (celebrity doubles) can always be found.

Even identical (monozygotic) twins display differences in features that enable them to be differentiated.

In forensic practice, the degree of individualization is highly dependent on the quality of the images (photos and videos) and the frequency of the identifiable features/traits. Due to the heritability of some features, close kinship can make the distinction of persons more difficult. Overall, a positive identification is very difficult to achieve and every feature has to be analyzed critically.

Established methods in forensic anthropology and classical criminology are used for the determination of individuality on the basis of facial and body appearances.

Despite the rapid advancement and increased practical application of DNA technology, the criminological importance

of image analysis has not diminished, especially due to the fact that more and more areas of daily life are under video surveillance and can, in principle, be controlled. The increasing anonymization of business life (ATMs) and increasing mobility (forged identity documents) create further potential applications.

The general aspect of a person is important; nonetheless, initially, the study of single traits can be very useful, before proceeding to a unified comparison of the entire physiognomy. As a result, the general appearance of a person on a speed-camera image, surveillance photo, or video can initially be separated into traits or features.

As in all morphological contexts of identification, for a high level of confidence, a large number of corresponding and/or unique features are required. If, for example, extremely rare features (skin lesions such as scars, warts, tattoos, or birthmarks) are present on the reference photograph, a lower number of features may be sufficient. Exclusion of identity, on the other hand, can be reached by the difference in one trait, if its evaluation was objective and if the discordance cannot be explained by other reasons, for example, surgery, and weight gain. On the other hand, in the case of a slight feature dissimilarity, the possibility of the dissimilarity being explained through lighting, image quality, contrast, masking, artifacts, etc., should be investigated.

The scientific methods of image identification were initially described in the German-speaking countries; this discipline has however gained, in the past decades, a widespread diffusion in international literature, and actually represents a relevant field of application of forensic anthropology.

Facial Assessment

Checking for Suitability of Images

Initially, the examiner must view the available evidence material. In the case of video recordings, it is vital that he or she analyzes the material and produces suitable still images. Photomaterial should – whenever possible – be requested in digital form. After a successful digitalization of the evidence material, an attempt at an improvement in quality can be made. This must be limited to brightness, tone, and contrast; must be understandable; and must on no account lead to feature alterations. At this point, the assessor should decide whether the reference photograph/image material is suitable for an assessment or the maximum level of confidence that can be achieved in an identification. One should keep in mind that there is always the risk of image deformation, especially in digital images. A transformation of the image format can lead to a modification of image proportions. These deformations can sometimes only be corrected by specialists (e.g., engineers). Even image compression techniques that are very common in the storing of digital images can lead to feature alterations. For that reason, one should be very careful with images that show a high compression rate.

Feature Analysis: The Preliminary Step

It is recommended that the reference photograph/image be carefully analyzed. The individual areas of the head (head

shape, face shape, facial proportions, hairline, forehead-, eye-, nasal-, mouth-, chin-, lower jaw-, cheek-, ear region, and neck) can be analyzed, described, and classified usually according to specific references, such as Interpol atlases or more modern and complete ones such as the DMV one (see Appendix). As far as the quality of the image material allows, an attempt is made in determining fine structures. Each feature complex is subdivided into numerous individual features. For instance, in the eye region these can be eyebrows, upper eyelid, distance between the eyes, eyelid axis, and lower eyelid.

Optical properties of the surveillance camera must be taken into account. In the case of surveillance cameras in ATMs, strong wide-angle lenses are often used to enable the capture of a wide area. Such ‘fish eye’ lenses lead to image distortions: whereas the central portions appear squashed, the structures in the edge areas appear bent or stretched. Once again, specialists in such cases should be consulted in order to correct, if possible, dangerous image distortions.

Comparison Image

For the assessment, a comparison image whose perspective matches that of the reference photograph should be available. Ideally, the comparison image should be prepared by the examiner himself. Only then can a safe, detailed, and reliable feature comparison be performed. Recordings from police identification records are standardized for their requirements and therefore often of limited use for an assessment. In addition, the dates when the reference and the comparison recordings were made must be taken into account, because alterations in the manifestations of features due to aging can have an effect to varying extents. Chronic illnesses can also change the appearance, whereby a relatively short time span between source and comparison photograph is required. Alterable features typically include hair style and beard style, and increase and decrease in weight. The possibility of previous surgery having taken place, as previously mentioned, must also be considered. In some cases, it may be necessary to record the comparison image with the same camera setup with which the evidence/reference photograph was made. In case an estimate of the height of the perpetrator is required, a reconstruction at the crime scene is required. The comparative images can also come from a 3D scan of the suspect, which would allow the examiner to virtually orient the 3D head and find the best-matching orientation subsequently on a computer. Feature analysis and classification can then be performed as mentioned for the reference photograph.

Comparison Analysis

After completion of the feature analysis of the reference photograph and of a suitable photograph of the suspect, a comparison can be performed. All the described features on the reference photograph are compared with all evaluated features and fine structures on the suspect’s image. The similarities and dissimilarities are described and discussed according to set standards (e.g., DMV atlas). As far as single traits are concerned, the examiner can verify the existence of discordant traits or that of similar ones. This step therefore will give an idea of consistency of the two faces, that is, of how similar they are. Positive identification should not, however, be attempted

at this point (and especially not on frequency and distribution of single traits among different populations).

Positive identification should be achieved once a global comparison of all traits and other more general features is performed. Different approaches exist. Some experts also use the superimposition of lines and general patterns on the images and verify the match. Another possibility is superimposing the face *in toto*. However, this is extremely laborious and requires a lot of equipment. In addition, overlapping techniques may have a suggestive effect. Any examiner using such a method must be aware of this. The use of 3D techniques is becoming more and more important: 3D-comparison images of the suspect can be much more easily adjusted to the perpetrator's face on a reference image and the geometric comparison may be more objective. The influence of the focal length and the distortion of the objective lens can be eliminated by using 3D laser scanning and optical surface digitalization. On the other hand, 3D scans are much more time-consuming than conventional photography. However, in many practical cases, only a combination of different techniques will lead to reliable results.

At what point, however, can one say to have reached identification, or how should the expert express his or her judgment? Unlike geneticists, the morphologist cannot respond in a quantified manner for obvious reasons. Forensic experts who deal with facial identification often are reluctant to define from a numerical point of view the strength of their results. However, many courts and judges often require some understanding of the strength of their conclusions; in 2003, the Forensic Imagery Analysis Group (FIAG), born within BAHID (British Association for Human Identification), established a common procedure for describing the level of ascertainment of personal identification according to the degree of support (provided exclusion has not been achieved):

- Level 0 Lends no support.
- Level 1 Lends limited support.
- Level 2 Lends moderate support.
- Level 3 Lends support.
- Level 4 Lends strong support.
- Level 5 Lends powerful support.

Many other 'classifications' exist. The problem still remains, however, just like with the anthropological or odontological identification of human remains, of what is enough for a positive identification beyond reasonable doubt.

Other Body Traits

Determining the height of the perpetrator

It has been mentioned above that the comparison of the stature of the perpetrator with that of the suspect can take place at the crime scene provided metric references exist on the reference photograph. Significant problems may arise concerning body posture, clothing, heels, etc., which must be taken into account. The procedure is, however, rather imprecise and therefore contains a large margin for error. For a negative identification in the case of an unusual height of the perpetrator, the procedure can be regarded as sufficiently secure. The most recent studies concerning this topic have highlighted that the reliability of height estimation in personal identification depends on the rarity of the estimated

perpetrator's height and its closeness to the suspect's height. As in the preparation of comparison photographs, the question as to whether there has been any change in the camera equipment in the meantime must be investigated beforehand.

Another method for height estimation consists of using a virtual telecamera with the same characteristics of the video surveillance system with which the images were taken. The experimental data showed an average difference between estimated and real height of about 10 mm, together with a standard deviation of 10 mm. This procedure obviously requires that the individual be represented in his entire figure from the feet to the head.

Gait analysis

In video recordings, gait is recorded alongside the body size. In the case of an unusual gait, this can lead to a narrowing down of the number of suspects or in the ideal case, to a positive identification of the perpetrator. The expert must however bear in mind that in a recreation of the sequence of events of the crime, the gait of the accused can intentionally be falsified. To prevent this, it has proven useful to film suspects when they believe that they are not being observed.

In addition, being systems based on the periodical nature of gait, they face clear limits when the subject is moving at a nonconstant speed and on a route which is nonlinear. Finally, these systems presuppose the analyses of sequences of gait, which usually cannot be defined by the few useful photograms of persons, taken during a generic walking phase. In addition, the entire methodology of gait analysis has not been standardized. Moreover, although gait can be considered an individualizing marker, the same individual can express different manners of walking according to different conditions (speed, mood, and environmental conditions). At the moment, gait analysis is a promising field of application, but still has to be standardized and thoroughly tested.

Age

The manifestation of facial features is, within certain limits, age dependent, although the modifications of facial features at different ages still need to be verified. During the growth phase, the main changes are in facial proportions from a child's to an adult's face; in addition, some measurements such as the ear length go on increasing after 18 years of age also. This may be used in the future to estimate the age of children and young people. In the last few years, increased attention has been given to the measurements of facial surfaces and volumes by the application of 3D image acquisition systems, which may be useful for the development of an age estimation method. However, further research is needed. Individual variability must however be taken into account. In adults, as the growth processes come to an end, facial modifications are due to natural aging, which however is less predictable, and therefore less applicable to a possible age estimation method.

Further Features on the Skin, Hands, and Genitals

Occasionally, no facial features are visible on images but additional features that could lead to an identification are visible. In general, only features that are unusual should be described.

Figure 1 (a) Comparison photograph. (b–e) Traffic surveillance pictures.

These could, for instance, be scars on a part of the body, anatomical anomalies, anomalies after accidents or illnesses, tattoos, piercings, etc. The pattern of skin veins, for instance on the back of the hand, has also been shown to be highly individual.

In conclusion, in order to identify persons on the basis of features, these must be visible and should not be affected by strong environmental influences or rapid age changes. A prerequisite for objectivity in identification is the clear definition of the features and the description of the different manifestations of features. A general limitation of the examiner's evaluation lies in the quality of the reference photograph. Often, very individual features such as scars, birthmarks, warts, etc. cannot be evaluated due to graininess, lack of contrast, reflections, unsuitable perspective of the image, or artificial masking. The examiner must decide whether the number of features and their manifestation are sufficient for a positive or negative identification. **Figure 1** shows surveillance photos of the same driver (senior author). The number of facial features and therefore the reliability of a feature comparison vary widely from photo to photo.

Appendix Morphological Assessment of Facial Features: The DMV Atlas

The following section shows the different areas of the human face, and deals briefly with the manifestations of the main

features, included in the DMV atlas, one of the most recent amplifications of the traditional Interpol standards. Listing all fine structures is beyond the scope of this review. Nevertheless, this limited list shows that the subfeatures of the main areas – face shape, hairline, forehead, eye region, nose, mouth area, cheek area, chin, and ear – can be divided into different feature manifestations. The following sections therefore describe the manifestation of some main and subfeatures of the human face, which are included in the atlas for the evaluation of facial features. The atlas describes a total of 46 facial features that have been scientifically studied and the frequency of different manifestations determined. Special emphasis is placed on user-friendliness. Take as an example the face shape: In the atlas only six face shapes are examined, which are well distinguishable from one another. More than 20 different face shapes are found in older anthropological literature, some of which even experts find hard to distinguish between.

Face Shape

Face shapes are classified as rectangular, oval, round, pentagonal with pronounced mandible, wedge-shaped, and pentagonal with pronounced cheekbones. Examples are shown in **Figure 2**.

Figure 2 Face shape classifications.

Figure 3 Forehead classifications.

Forehead

The height of the forehead is classified relative to the height of the entire head (trichion–sellion). The breadth of the forehead is expressed in terms of the complete head. Possible descriptions for the frontal height are shown in [Figure 3](#). Seen from the side, the forehead bias can be described.

Frontal Hairline

The shape of the hairline in frontal view can be described as shown in [Figure 4](#).

Eye Region

The human eye region contains many features. Eyebrow height, eyebrow density, which can be medial or laterally pointed, and eyebrow shape can be described. There may be a mono-brow which is shown in [Figure 5](#). The distance of

upper eyelid–eyebrow in comparison to the complete face can be described as well as the lid axis, the size of the visible eye, and the distance between the eyes.

Nasal Region

The nasal region contains numerous subfeatures that can provide important information for positive or negative identification in the case of good-quality images.

The nose bridge length is defined as the distance between nasal root and nasal tip (sellion–pronasale) in comparison to the complete face. The breadth of the nasal bridge is described in comparison to the complete nose in frontal view. Nose bridge process describes the run of the nasal bridge in frontal view. The nose profile must be estimated from a lateral view. The orientation of the nose tip is defined as the location from pronasale to subnasale in lateral/frontal view. In frontal view, the nose tip shape can be specified. In lateral view, the nose protrusion (in comparison to the complete face) can be

Figure 4 Frontal hairline classification.

Figure 5 Mono-brow classifications.

described (Figure 6). In frontal view, the nasal breadth is expressed as the degree of puffing of the alar wings (al-al). The length of the skinny alar wings in comparison to the complete nose in lateral view is called alar wing length. In lateral view, the nostrils can be specified.

Oral Region

The distance between upper vermillion and the nasal baseline (labiale superius–subnasale) is called the philtrum height (Figure 7). The degree of impression between lips and nose is called philtrum depth. Labial breadth is expressed as the

distance between the corners of the mouth (cheilion–cheilion) in comparison to the complete face in frontal view. The shape of the upper rim of the vermillion (upper lip notch) can be described as well as the angle of the outer ends of the mouth slit.

Chin Shape

The form of the chin contour can be evaluated. The degree of transition from chin to the basis of the mandible can be described. In lateral view, the chin protrusion can be specified (Figure 8). Some individuals show a dimple in the chin. The height of the chin may also be differentiated.

Figure 6 Nose protrusion in lateral view.

Figure 7 Classification of philtrum height.

Figure 8 Protrusion of the chin.

Figure 9 Attachment of the ear lobe.

Figure 10 Wrinkles and dimples.

Ear Region

In addition to the main features such as pinna and earlobe, the human ear contains a wide range of highly differentiated fine features, which can be very typical for an individual. Unfortunately, in practice, the quality of the reference photographs usually only allows an evaluation of the gross structures.

The distance from the highest to the lowest point of the ear in lateral view (superaurale–subaureale) in comparison to the complete head is called ear height. The distance from the most anterior to the most posterior point of the ear (praeaurale–postaurale) can be described. The size of the earlobe is evaluated in comparison to the complete ear. The degree of attachment of the ear lobe is shown in [Figure 9](#). In frontal view, the degree to which the ears stick out (ear protrusion) can be judged.

Cheek and Throat Area

Depending on the subcutaneous fat tissue and bone structure, the cheek and throat area can be differently manifested. The cheek region can be extremely sunken (gaunt) or extensively to roundly padded. Flat depressions or ‘fleshy pockets’ may be present. In the chin–throat area, a double or triple chin may be present. A depression below the cheekbones in frontal view may be visible.

Wrinkles and Dimples

As [Figure 10](#) shows, wrinkles and dimples can give the human face very individual, sometimes individual typical, traits. Precise definitions are required to describe these features, and these are also provided in [Figure 10](#).

Glossary

Cementum A bone-like tissue covering the roots of teeth providing anchorage for a periodontal ligament which is inserted into the bone of the jaws to attach the teeth.

Dental enamel The hard translucent covering of the crowns of the teeth comprising 96% by weight skeletal mineral.

Dentine The tissue forming the bulk of the tooth containing within it a soft-tissue pulp upon which this tissue relies for

its nutrition and its capacity for repair in the face of environmental challenge.

Orthopantomogram A type of radiographic image used widely in dentistry to provide a panoramic radiographic image of a person's upper and lower jaws and teeth simultaneously.

Radiograph The correct term for an image produced by x-rays on some form of recording medium, often photographic film.

Definitions

In the context of this encyclopedia, 'odontology' is synonymous with 'forensic dentistry' and 'forensic odontostomatology.' None of the terms is really adequate for what is today one of the fastest-emerging micro-specialties within the broader subject of dental science. Nevertheless, as all of the somewhat limited definitions imply, a forensic odontologist is someone who understands the significance of the conjunction of the law and dentistry and can therefore explain the complexities and subtleties of dental evidence to the courts. This capacity to report on findings and then progress to express an opinion relies upon the courts affording expert status to the witness. In the adversarial systems of justice, this may require the expertise to be established on each occasion to the satisfaction of the judge from the outset. In a practical sense, it is the combination of education, training, and experience appropriate to the case currently before the court that is scrutinized, and so track record has a major part to play in the decision.

The forensic odontologist has to be not only an experienced licensed or registered practitioner of clinical dentistry but someone who is also able to observe, record, gather, preserve, and interpret dental evidence, and who is then able to make it meaningful within a legal context. In common with all good expert witnesses, this requires special skills, such as the ability to communicate clearly and simply by word and in written reports.

The Nature of the Work

In Victoria, Australia, a state of approximately 5.5 million people, the casework is roughly typical of that encountered in many modern, technologically advanced, prosperous, urbanized, industrialized societies. While tens of thousands of coronial autopsies are conducted every decade, only a few hundred cases (~2.5% of all autopsies) need forensic dental expertise to assist the investigations. Of these, ~90% require the corroboration of a putative identity by comparison with existing antemortem dental records or the establishment of broad indicators of identity when no antemortem records exist

or can be located. In most cases, the injuries to, or decay of, the body precludes visual identification. Incineration of remains is the most common cause of disfigurement followed by decomposition, severe trauma, and skeletalization.

Therefore, while forensic odontology increasingly encompasses cases dealing with issues of causation of injuries and assessments for the quantum of damage where compensation is sought by a victim of assault or injury, relating to claims of negligence or malpractice by dentists and related professionals, the main thrust of day-to-day casework still remains primarily that of the corroboration of identity of deceased persons. Historically, there are numerous accounts of famous persons being identified postmortem by recognition of certain peculiarities within their dentitions. In more recent times, in the aftermath of major catastrophes, both natural and manmade, including the aftermath of civil conflict and war, the use of forensic dental expertise in disaster victim-identification teams has been shown to be extremely effective and much less expensive and time-consuming than other methods. The involvement of forensic odontological expertise in the investigation of state-sponsored violence and acts of genocide against populations and acts of genocide has focused sharply on the ethic and moral foundations that underpin the work of all health-care professionals who identify the dead for the sake of the living and provide irrefutable evidence for the historical record.

Why Is Dental Evidence So Good for Corroborating Identity?

Everyone has teeth. When they do not, it is common for people to wear prostheses. If they have never developed teeth, this is, in itself, so unusual as to be highly individualizing and may be only one manifestation of a syndrome with other, more obvious, physical signs.

The form of teeth and the detail of their arrangement in the dental arches provide a body of information that is probably unique to the individual. Even in identical twins, the slight variations in tooth form and position can enable the twins to be separated on the basis of their dentitions.

Add to the above criteria, the almost infinite variation that can be added to the dentition by way of dental treatments (extractions, unique handmade dental restorations, and different use of restorative materials, prostheses, and orthodontic appliances) and the dentition is certainly as individual as a fingerprint.

One great advantage over fingerprint evidence for the corroboration of identity arises from the resistance of the oral structures to fire or putrefaction. Teeth and bone can be heated to temperatures approaching the melting point of skeletal mineral ($>1600^{\circ}\text{C}$) without appreciable loss of microstructure or tertiary architecture. Furthermore, the teeth represent the only part of the skeleton that normally protrudes from the soft tissues of the body and is therefore available for examination and recording by photography or dental impressions before death.

This accessibility is the second advantage of dental evidence over fingerprints, particularly in societies where the taking and retention of fingerprints from persons is strictly limited to those with an existing criminal record. Similarly, much medical treatment returns the patient to full health with no residual indicators of a temporary disease permanently expressed; a sore throat is a transient event that leaves no scar and therefore nothing permanent and tangible with which postmortem comparisons can be made. Conversely, when some medical procedures, such as orthopedic surgery for a prosthetic hip replacement, are performed, the resulting records in all their forms are excellent for identification purposes (Figure 1). Unfortunately, for identification purposes, such treatments are still not commonplace but their placement in an aging population is certain to increase.

By comparison with such still relatively uncommon surgical treatment, almost everyone in the developed world has had to attend a dentist for a dental checkup or treatment at some time in his or her life. The attendance at the dentist inevitably results in the production of records. All are potentially valuable. These may be in the form of written clinical notes and odontograms (dental charts), plaster casts of the dentition or radiographs ('x-rays'), or, less usefully, even just an itemized bill for payment. Worldwide, the standards of record keeping are highly variable. Broadly speaking, the more prosperous and developed the society, the better are the standards of record keeping, but there are exceptions. In the absence of comprehensive written or graphical records, the contribution of 'dental x-rays' to the process of corroborating identification can hardly be overstated.

Even when no treatment has been carried out in the form of dental restorations or 'fillings,' x-rays may have been taken to check for the presence of tooth decay at hidden and inaccessible sites such as the contact points between adjacent teeth at the back of the mouth, or to monitor the progress of periodontal diseases. In addition to the specific clinical need to take the x-ray, the resulting radiograph conveniently records many, normally inconsequential, features of the dentition and jaws. These characteristics include the size and shapes of tooth roots, dental restorations, and the pulp chambers within the teeth. The internal architecture of the bones of the jaws is often clearly revealed and may show the internal struts of bone, called trabeculae, the presence of healing tooth sockets post-extraction, the retained roots of teeth, or the crypts containing

Figure 1 (a) Postoperative radiograph of a prosthetic hip joint. When such permanent evidence of medical treatment exists, it is excellent for corroborating the identity of a body even where there has been no putative identity developed. The type and unique serial number of prosthesis can lead to an immediate identification when national registers exist to monitor all joint replacements, as is the case of Australia. Similarly, the gage of the wire, the number and nature of the turns, twists, and loops in it, taken together are a signature of the operating surgeon and provide a unique image for comparative purposes. Such images are not as commonplace as dental records and x-rays. (b) This is the oro-dental equivalent of (a). A panoramic antemortem radiograph that reveals internal fixation of a reduced mandibular fracture. None of this metallic surgical material was seen at dissection, being completely internalized within the jaw after a long period of healing.

developing teeth (Figure 2). In larger radiographs, such as those depicting panoramic views of the jaws (orthopantomograms – OPGs/or more strictly OPTs in dentists' jargon), the details may be less clear but there is a compensating increase in the number of structures imaged. These include the maxillary sinuses of the skeletal complex of the upper jaw. The paranasal sinuses are air-filled spaces or pneumatizations of the skull, all in communication with the upper respiratory tract, which increase in size during early life but then stabilize in adulthood (Figure 3).

Similarly, when x-rays are taken of the whole head, other sinuses that have formed within the bones of the forehead

Figure 2 A pair of intraoral 'bitewing' radiographs. These are the most common radiological views of the mouth, routinely taken by dentists to check for tooth decay or the presence or progress of degenerative disease in the supporting tissues of the teeth. Such images also serendipitously reveal the state of dental maturity in the young and summarize much of the restorative dental treatment experienced by the individual throughout the life. In these particular radiographs, the crowns of the as-yet-unerupted wisdom teeth can just be seen. The form of the other teeth, specifically the shapes of their roots in their sockets and the internal pulp chambers, is clearly seen. This patient has had eight dental amalgam restorations. Each restoration has a unique silhouette for any given geometric/radiographic projection.

Figure 3 Three panoramic radiographs (orthopantomograms, OPGs). (a) Radiograph from a child aged about 8 years. It shows a mixture of deciduous and permanent teeth erupted and functional within the oral cavity. Beneath them, within the jaws, there are many successional teeth developing in crypts. Knowledge of the chronology of tooth development and emergence sequence for the dentition allows age estimation to be undertaken with reasonable certainty during the first two decades of a

(the frontal sinuses) may be displayed. The size and shape of sinuses are very variable. Furthermore, they are often partially divided internally by walls or septa whose position is also stable and which are clearly visible on x-ray. The combination of these two features means that x-ray images of the sinuses can be excellent for comparison with postmortem findings, when the sinuses can be repeatedly x-rayed in slightly differing orientations until direct visual comparison of similarities and differences validates a 'match.' To achieve a valid match, and therefore a 'positive identification,' all the features of interest must coincide simultaneously with all other features depicted on both radiographs. This requirement is an important check and a good internal standard to ensure that a match of important features has not been unwittingly created. The process of comparison can be done by eye by directly overlaying antemortem and postmortem radiographs, or digitally by subtracting one image from the other when all that remains is that which is different between the two views.

Sometimes, the radiographs to be compared may look quite different from each other and yet yield evidence of a match of certain features. A good example might be if some teeth were present in the antemortem clinical x-ray image, yet missing in the corresponding postmortem view (perhaps lost per mortem as a result of trauma or putrefaction). Supposing the feature to be compared was the shape and form of the sinuses, then, provided the tooth socket outlines still matched in size, shape, and position, the missing teeth would not matter nor would it invalidate the match.

person's life. (b) Radiograph from a middle-aged person aged 50. The patient has had multiple root canal treatments, during which finely tapered gutta percha points have been cemented into the root canals of several teeth. This style of treatment is now rather outdated. The combination of many dental restorations and root fillings has produced a unique pattern of features that is invaluable for identification purposes. (c) A radiograph from an elderly person aged 80. The natural teeth have all been extracted many years ago and full dentures have been worn ever since. This OPG reveals the presence of a single, completely formed tooth unerupted in the right maxilla. This tooth, previously undiscovered, has been buried within the jaws since the time of its initial formation over 60 years ago. The presence, form, and position of the unerupted tooth, taken together with the myriad of other anatomical features depicted simultaneously, are unique.

Another potential complication can arise from the passage of considerable time between the taking of the antemortem x-ray and the taking of corresponding views postmortem. This is particularly the case if the antemortem record has been taken when deciduous (baby) teeth are still present, but the postmortem views are not taken until those deciduous teeth have been shed and replaced by permanent successors.

This serves as a good example of why an expert opinion is necessary to explain to lay people, which includes lawyers within the legal system, that, although the images look different, they are really of the same person, but just taken at different stages of their life, which is explicable if the chronology of dental development is understood and explained clearly (Figure 4).

When No Antemortem Records Exist

So far, the assumption has been made that antemortem records exist and, once located, can be used for comparison with postmortem findings. However, records are not always traceable, or retained. In about a third of cases in Victoria, Australia

Figure 4 A homicide case where the mandible is the only part of the skull to have been retrieved after prolonged immersion of the body. (a) The lateral oblique view of the recovered skeletalized mandible shows a very unusual developmental malpositioning of the mandibular premolars. The malformation was bilateral. (b) Two lateral oblique views (left and right) of the same person taken during life by the school dental service. The misplaced premolars can clearly be seen on both sides of the jaw. More teeth are present in these earlier clinical radiographs, but the difference between (a) and (b) is explicable when the intervening period is taken.

(a state with high immigration), no records are available for the odontologist to use as a basis for comparison. In such cases, what inferences can be made?

Teeth develop in a predictable sequence, which enables age to be estimated during their formation with reasonable accuracy. This period extends from midfetal life until the attainment of physical adulthood in the early part of the third decade. In the absence of birth records, the eruption of second permanent molars formed the basis upon which children were deemed old enough to work in factories during the industrial revolution in Britain in the early 1800s – a nationwide forensic application of dental knowledge affecting the lives of millions. During adulthood, the teeth and their supporting tissues undergo progressive changes. These can be greatly influenced by diet, habits, customs, and lifestyle. In this context, the front-line task confronting the forensic odontologist differs little from any discipline concerned with reconstructing past events from incomplete evidence and the interpretation of their significance. In archeology, paleontology, and biological anthropology, there is inevitably an imposed reliance upon inference and comparison with accumulated knowledge rather than a direct ‘concrete’ comparison between records and findings. The results of such inferences need to be carefully presented to avoid the impression of unwarranted certainty. Comprehensive accounts of the determination of ancestry, gender, and age from the orofacial structures have been published (Figure 5).

For example, in the 1960s, Gustafson consolidated many of the age-related changes of teeth into a unifying series of age-predictive regression equations. He scored the progressive infilling of the dental pulp chambers by secondary dentine, attrition caused by tooth-to-tooth contact under the influence of the diet, compensatory cementum deposition on tooth roots, the migration of soft-tissue gingival attachments, and increasing translucency of dentine due to increased peritubular (strictly, intratubular) dentine deposition. Several

Figure 5 An archeological specimen. This mandible was found on the Chatham Islands east of New Zealand. The specimen carries a history of a fracture that at one time split the body of the mandible lengthways. Teeth were lost in the fracture line, either at the time of the injury or during subsequent infection before eventual healing. The bony fragments are misunited because the fracture was never reduced by a doctor prior to bony repair. As a consequence of the loss of teeth, the man was obliged to chew on one side of the jaw only. Those teeth show heavy attrition. Taken together, these derangements have almost certainly led to the osteoarthritic degeneration of the jaw joint on one side. From the above observations and inferences, it would be highly unlikely that this person would have lived in the last 100 years. The find is therefore of little interest in a coronal context.

other researchers have critically revisited and revised all or part of Gustafson's method, introducing minor modifications from time to time (Figure 6). In essence, Gustafson's method was probably successful at that time because of the homogeneity of his Swedish sample in terms of ancestry, genes, social and lifestyle factors, and diet. The methods are of much less use in countries such as Australia, where there has been recent, large-scale immigration from many different places by peoples of different ancestry, each with their own cultural overlay of past diet, habits, and customs.

Of all the age-related factors described above, the increasing translucency of dentine with age is probably the most physiologically related and hence the least affected by environmental influence.

In common with other products of complex epithelial/mesenchymal interactions, such as fingerprints, the teeth also reveal evidence of heritability in some of their features. This results in ancestral differences of 'ethnic traits' in the dentition, which can be of forensic importance. Anthropologists who study populations rather than individuals for evidence of individual identity tend to use large numbers of physical measurements to investigate 'ethnic traits.' This metric approach has spawned many studies on tooth crown dimensions, often from plaster casts obtained in the field or directly from living individuals over a period of time. The results are of limited forensic value where there is a much greater emphasis on individuality and unique identifiers.

Figure 6 Age changes to the teeth. This longitudinal section through a tooth has been x-rayed to produce a microradiograph. The tooth came from a middle-aged person. It shows attrition through the enamel to dentine, and the vital reactionary changes in the underlying dentine. The cervical margin (neck) of the tooth reveals cervical abrasion after gingival recession has taken place. To compensate for the loss of enamel from the crown due to wear, more cementum (a bone-like substance) has been deposited at the tip of the root. These and other changes were those quantified by Gustafson.

Interactions with Other Professionals

For the majority of cases, it is expected that the odontologist will form part of a team of investigators. Such teams may comprise a pathologist, police investigators and scene of crime personnel, mortuary staff, photographers, sculptors, artists, and other experts, such as entomologists, molecular biologists, or accident investigators. In cases where living victims of assault have to be examined and treated, the composition of the team will differ but is likely to include hospital doctors, nurses, and the staff of the local government social services department.

Whatever the composition of the group, clear lines of responsibility and reporting need to be understood by all involved from the outset. The coordinator/facilitator/leader (usually the most senior police officer) has to have a clear overview of the evidential requirements for the entire investigation and to be aware of the sometimes conflicting requirements of the investigators. For example, it would be a catastrophe for the forensic odontologist to adopt the policy of slavishly resecting the jaws of deceased victims, just in order to make examination of the dentition easier, if the only available evidence that would have corroborated identity required the facial skeleton to be kept intact. While on this point, it is also important to note that such a procedure should only ever be undertaken if disfigurement of the face is already so extreme that viewing of remains by next of kin would be advised against, or where a truly expert dissection and reflection of facial tissues can be done and then replaced over the skeleton after the dental procedures have been completed. This may take the form of inspection of the teeth and jaws in situ, an inspection of the teeth and jaws after excision, followed by their replacement or the permanent removal of the jaws. The structure and form of the face are then restored by the insertion of prosthesis. Groups that comprise experts who understand each other's skills, perhaps because they have worked together on numerous occasions in the past, undertake the best investigations, but in all cases, it is important for each expert to know what is required of him or her. A case conference at the outset of a multidisciplinary investigation quickly repays the time and energy expended by assuring efficiencies and precision later on. Sometimes, what was initially seen as an apparently uncomplicated 'deceased person identification,' undertaken on behalf of the coroner, can later be discovered to really be an event requiring a full homicide investigation. In many jurisdictions, the evidential requirements for different courts differ in their rigor. In the UK system of justice, and many of its derivatives around the world, the coroner requires proof of identification only 'on the balance of probability,' whereas a higher court which may have to try an accused person facing a charge of murder requires identification to be established more stringently 'beyond reasonable doubt.' It is therefore important for the forensic odontologist to anticipate where every case may lead and to conduct their investigation with the final forum for their deliberations clearly in mind.

Bite Marks, Bruising, and Other Injuries to Skin

Forensic odontologists are frequently called to look at people, both dead and alive, or objects which may retain 'tool marks'

left by an interaction with the teeth of a person or an animal or animals (or something which closely resembles such marks). The circumstances range from excellent, clearly identifiable, bite marks left by an individual in a dimensionally stable substrate such as hard cheese or chocolate, to the badly mauled, barely recognizable remains of a deceased person killed by a large carnivore or carnivores (Figure 7). The situation can be even more difficult if the case is one involving postmortem animal predation of the corpse, where scattering of the remains and superimposed decomposition add complexity. Where a person has been mauled to death and the animal thought to have caused the injuries can be caught or killed, it is relatively simple, by the use of emetics or dissection, respectively, to prove the involvement of the animal. In instances where humans bite other persons, it is uncommon for large pieces of tissue to be removed. The marks remaining from the bite may range from an excellent silhouette of the dental arches and individual teeth to something very diffuse and indistinct; the latter case is unfortunately the far more common circumstance, especially if there has been a delay prior to the collection of photographic evidence.

The poor fidelity of human skin as a recording medium, its deformability and elasticity, its capacity to heal, and the curved nature of the external surface of the body, added to the complex form of the dental arches and the many possible movements of the jaws during biting, combine to make scientific analysis of bite-mark injuries very problematic. While there are a growing

number of noncontact, three-dimensional surface scanners that can accurately record curved three-dimensional shapes and skin color and texture for analysis that are being introduced into clinical environments, they are not yet widely available. As current police procedure requires many possible bite marks to be investigated on living victims, some very distressed, in the technologically restricted environment of a hospital accident department or, worse, in a police station, the use of sophisticated technology is not possible. The odontologist then has to try to interpret much less informative primary sources of information such as two-dimensional photographs of what are always three-dimensional injuries. It is this constraint which has led to some conspicuous errors of interpretation that in turn have led to wrongful convictions, some only overturned years after the event on the basis of a later DNA analysis of evidence originally collected from the crime scene. Where the injuries are less severe and/or more diffuse, photography may still be the only practical method for documenting the injuries. Ultraviolet or infrared light beyond the visible spectrum can be used to produce images that reveal bruising, which may be undetectable using visible light. Exactly what histological or chemical changes to the skin enable these images of old and/or 'latent' bruising to be made still have to be determined and again interpretation can be controversial, particularly as it may be impossible to separate tissue changes induced by both recent and past injuries to the same part of the body.

Without the foundations of fundamental scientific knowledge about the biology and chemistry of bruising, and the ability to model accurately the actions of the teeth and jaws interacting with the soft tissues of the body in a realistic, dynamic way, the presentation of bite-mark evidence to the courts will remain problematic.

Where some topography in the form of indentations, cuts, abrasions, or exudates can be found on the victim, the recording of bite marks is customarily done by means of dental impression materials and swabs for biological analyses. Impressions taken from such injuries are used to make rigid models in plaster or dental stone. These models can then be used for comparison with the dentition or models of the dentition of the suspected assailant (or victim if a self-inflicted injury is possible). Photographs usually augment the use of such models.

In Australia, bite-mark evidence has become so discredited in the wake of two prominent cases that drew heavily upon the opinion of foreign experts, and in which it was later judged that some of the experts must have misinterpreted their observations despite coming to the same conclusions, that in a subsequent protocol established for the taking of 'intimate samples,' bite-mark evidence was considered to be of little value. This unfortunate extrapolation overlooks the great exculpatory value of bite marks to an investigation and the justice system. By way of contrast, in South Africa, a country suffering from high rates of interpersonal violence, bite-mark interpretation is carried out routinely and the courts accept the evidence proffered by the odontologists.

Other Skills

Implied in the previous section is a requirement for the forensic odontologist to have a comprehensive knowledge of

Figure 7 Shark bites. (a) A life jacket recovered after a yacht was lost. The jacket carries serrated bite marks left by a large shark. (b) (See color plate XYZ) A postmortem shark bite on the remains of someone who had already drowned. The arcing lacerations with regular spacing are quite typical of a medium-sized shark.

comparative dental anatomy. At its most obvious, there is a common need to be able to sort animal remains from those of human beings. While some anthropologists and archaeologists are experts in this, very few understand the dentition as well as their dental colleagues, particularly where only particulate remains or fragments of skeletal material are found and a study of microstructure is required. An expert knowledge of the differences in microscopic tooth tissue structure between different genera is particularly important in forensic cases where a consumer alleges contamination of foodstuffs. Further, in those countries where people are still killed by wild animals, it is important to be able to recognize the characteristic pattern of injuries inflicted by the local predators.

Summary

At this time, forensic odontology remains one of the most reliable, cheapest, and quickest means of corroborating human identity (Figure 8), especially in the wake of mass disasters for victim identification. By its very tangible nature, it is easily presented to, and understood by, juries. Twenty-five years ago, anticipating many of the identification tasks would be more likely to be answered by advances in molecular biology, and realizing that DNA evidence would become more reliable and, more importantly, less controversial in court, it was widely assumed that the future of forensic odontology would be very limited. This has not occurred. For a variety of reasons including poor crime scene and continuity of evidence management, technical difficulties with contaminated or degraded samples, and difficulty of obtaining reliable reference samples for comparison, DNA analysis is still of much less practical value than dental comparisons for corroboration of identity in disaster victim-identification situations. Forensic odontological methods are quick and cheap by comparison, which is an additional advantage. Age-at-death determination from predictable and progressive changes to the organic matrices of hard tissues is a technique that has not yet become widespread, despite important ongoing studies showing its feasibility in the hands of a very small number of exponents.

However, while much of what is done today may still be in the ascendancy, other aspects of the work of the forensic

odontologist may soon become redundant. Forensic sculpting to recreate an approximation of the facial features of the deceased utilizing remnant skull evidence, a once popular technique of last resort, has a limited future for several reasons. There have now been numerous studies and practical examples of the wide divergence in the results obtained by different practitioners when multiple reconstructions have been made from the same skull and contextual information. These results sit uneasily with the evermore rigorous scientific scrutiny demanded of most forensic activities by the courts. However, perhaps the greater challenge to the validity of facial sculpting will come from modern mathematics and engineering where statistical approaches derived from combined data sets of surface scanning of facial features integrated with computed tomography (CT) images of the underlying skeleton will permit the automated generation of the most plausible face to fit upon any CT or laser topographic scan of an unknown skull projected into the statistical framework. There is a large degree of overlap between these morphometric approaches and psychological research into facial distinctiveness, memorability, and recognition, with all its cultural and same race/other race overtones.

The very precise anatomical modeling of human skeletal remains, to be used as *aides-mémoires* for the pathologist and as court exhibits long after the interment or cremation of the deceased, has its basis in dental materials and technology. These skills will only remain in high demand until the rapidly emerging technology of three-dimensional printing becomes commonplace and thereby inexpensive. This trend has begun and the landscape will be transformed very rapidly.

However, to return to our fundamentals, the forensic odontologist is a person with dental qualifications and clinical expertise who also has considerable experience of the law and courts and issues relating to the ethics and the conduct of the dental profession at large. It is commonplace for police faced with allegations of professional misconduct or charges of physical or sexual assault at the hands of a dentist in a clinical setting to consult the forensic odontologist. Investigators see him or her as a sound, balanced, and broadly experienced professional peer, who understands what is deemed to be acceptable contemporary clinical behavior in dentistry before considering whether a *prima facie* case exists that warrants further investigation and a possible prosecution.

The investigation of illegal, unregistered practitioners, and the premises from which they operate, rightly involves the forensic odontologist, who is able to advise on health and safety aspects for the on-scene investigators and the legal status of prescription medicines recovered at the scene. These are but two examples, but other important issues pertaining to consent to treatment, confidentiality, access to records, malpractice, litigation, risk minimization, and evidence-based practice are subjects to which much more prominence has been devoted in newer medical school curricula where departments of legal medicine have been newly established. These developments are now being mirrored in dentistry, and consequently the forensic odontologist will rightly be in the vanguard of such advances and the benefits they bring to our society.

Figure 8 An anatomical replica in methylmethacrylate, made with dental techniques for use in a courtroom demonstration by the pathologist years after the interment or cremation of the remains. Three-dimensional replicas are much more successful than two-dimensional photographs for displaying osseous injuries, such as hatchet wounds or bullet trajectories. Glossary

Autoerotic asphyxia The deliberate induction of hypoxia with the intent of causing heightened sexual arousal.
Autoerotic behavior Sexual self-stimulation that can involve a device, apparatus, pornographic material, prop, chemical, or behavior that is engaged to enhance sexual stimulation.
Autoerotic death When autoerotic behavior is the cause of death.
Crime scene investigation Crime scene investigation includes crime scene examination and documentation,

laboratory analysis of physical evidence, scientific interpretation of results, and scientific reconstruction.
Hypoxia Partial oxygen deprivation; oxygen deficiency (as opposed to total oxygen deprivation).
Masochism Sexual arousal from punishment, bondage, discipline, humiliation, or servitude.
Psychological autopsy The process that death investigators and mental health experts use, in collaboration, to determine the state of mind of a person before they died.

Sexual fatalities are deaths that occur as the result of, or in association with, sexual activity. They include deaths that occur during consensual sexual behavior, deaths that occur

during criminal sexual homicides, and accidental deaths that occur as a result of *autoerotic behavior*. In order to serve justice, it is important that crime scene investigators have the tools to

discriminate between such cases – to avoid misinterpreting consensual sexual activity as a criminal act, or an accident as an intentional suicide.

Autoerotic asphyxia is the deliberate induction of hypoxia (partial oxygen deprivation) with the intent of causing heightened sexual arousal. An *autoerotic death* occurs during autoerotic behavior in which a device, apparatus, prop, chemical, or behavior that is engaged to enhance sexual stimulation causes death. Conservative estimates suggest that between 500 and 1000 autoerotic fatalities occur each year in the United States alone. However, given the potential for misidentification, the true number is likely higher.

The Literature

In 1983, Hazelwood and Dietz's study of 157 cases of suspected autoerotic fatalities gave the following breakdown: 132 (84.1%) asphyxial (i.e., typical); 18 (11.5%) atypical; 5 (3.2%) asphyxial with a partner; and 2 (1.3%) autoerotic suicide. Uva, in a review of autoerotic asphyxial deaths in the United States, reports that the incidence of such deaths is increasing, when, in fact, it may be only that the reporting or identification of such deaths may be increasing. Most cases involve young males, but the age range is large.

In 1991, Blanchard and Hucker's study of 117 male autoerotic deaths in Canada gave a range of 10–56 years, with a mean of 26 years. A third of the men were under 19 years of age. In 1995, Behrendt and Modvig, reporting on 46 male autoerotic deaths in Denmark, gave an age range of 10–71 years, with a mean of 31; 64% of the men were younger than age 29. Another study reported that 31% of the adolescent hangings in a section of Minnesota from 1975 to 1985 were autoerotic asphyxial deaths.

Since the time of these studies, the literature on autoerotic death has advanced little, and has comprised primarily of case studies and vignettes. In 2006, Sauvageau and Racette published a 50-year retrospective study of these cases in the literature, from 1954 to 2004. They found that, anecdotally, the most common methods of autoerotic activity that lead to death are asphyxia from hanging, ligature, plastic bag, chemical substances, or a combination of these. Furthermore, they found that atypical methods of autoerotic activity that lead to

death can be regrouped into five general categories: electrocution, overdressing/body wrapping, foreign body insertion, atypical asphyxia method (e.g., chest compression, inverted or abdominal suspension, immersion), and miscellaneous. Atypical cases were found to represent about 10.3% of all published cases.

Sauvageau subsequently reviewed all autopsy cases performed at a single centralized forensic laboratory that covers an entire 7.5 million province population for autoerotic deaths over a 7-year period (2000–06). This study found that comparing this population to the data in the literature, "it seems that incidence of autoerotic deaths may no longer be valid. As for atypical cases, they may be more frequent than generally assumed" (p. 2). This study was not without limits (e.g., does not account for misidentified cases), and may not be generalizable to the United States owing to differences in culture and media coverage, but it points to the need for more updated research in this area.

The Nature of Autoerotic Death

Autoerotic death scenes can be mistaken for either a homicide or a suicide. They are in fact largely accidental in nature. There are certainly some cases in which the victim intended to commit suicide by autoerotic means, but these cases have been few. When an autoerotic fatality is identified, it should be assumed accidental in manner unless there is strong evidence to the contrary. Furthermore, autoerotic fatalities are not the result of criminal behavior, and should not be treated as crimes. Once a determination of autoerotic fatality is made, law enforcement may no longer be required to investigate the matter further.

The sexual pleasure sought by individuals who engage in autoerotic activity is primarily achieved through a combination of physical and psychological stimulation. These sources are not exclusive of each other. For example, the behavior of masturbation is physically gratifying; if the individual places a mirror so that they may observe themselves masturbating, then this becomes psychologically gratifying as it fulfills a visual fantasy need.

The danger in autoerotic activity arises when an individual acclimates to their current sexual stimulus and starts to do

Table 1 High-risk elements in autoerotic behavior

High-risk element	Device/apparatus	Props	Chemicals
Examples	● Asphyxial ligature (rope, belt, cord, etc.) ● Complex ligature ● Duct tape for mummification ● Electrical wires attached to the body ● Fire (sexual immolation) ● Immersion in a bathtub ● Plastic bag over the head ● Power hydraulics ● Restrictive bondage	● Firearm ● Knife ● Sharp, oversized, or unclean fetishized objects inserted into orifices (bolts, large cucumbers, oversized dildos, etc.) ● Vacuum cleaner attached to or inserted into the body	● Amyl nitrate ● Cocaine ● Freon ● Gamma-hydroxybutyric acid ● Methamphetamine ● 3,4-Methylenedioxymethamphetamine MDMA (Ecstasy) ● Nitrous oxide ● Propane ● Tetrachloroethylene

things that put their life at risk. To achieve an increasingly enhanced state of physical or psychological pleasure, an individual may begin to employ a high-risk device, apparatus, prop, chemical, or behavior that puts their life in danger. The more often an individual uses dangerous, high-risk elements during autoerotic behavior, the greater the chance that their practices will result in an autoerotic death.

Table 1 shows examples of high-risk devices, props, and chemicals found in published cases of autoerotic death. The term high-risk may be subjective to the health of the victim. The term *device* or *apparatus* refers to any items that an individual uses or adapts for physical pleasure. The term *prop* refers to any item that an individual uses or adapts for psychological pleasure (fantasy). Items can be both a device/apparatus and a prop (devices can easily become fetishized over time), and items can be used in combination with each other. The term *chemical* refers to any chemicals or drugs used that are intended to enhance sexual arousal during autoerotic behavior.

Autoerotic Asphyxia

The most common form of *autoerotic death* results from *autoerotic asphyxia*. Asphyxial deaths are caused by a restriction of oxygen to the cells. There are three general categories of asphyxial deaths: suffocation, strangulation, and chemical asphyxia. Autoerotic asphyxia most commonly takes the form of self-induced hanging, including deaths caused by or in association with strangulation and chemical asphyxia. Hanging is a form of strangulation where death is caused by compression of the blood vessels in the neck. The compression results in an insufficient amount of oxygenated blood reaching the brain.

This pattern of repetitive sexual self-gratification is referred to as *asphyxiophilia*, *hypoxophilia*, or *sexual asphyxia*. It is also referred to as *autoerotic asphyxia syndrome*. Those who engage in this dangerous, repetitive pattern of sexual behavior typically

intend to achieve physical pleasure. The physical pleasure comes from a temporary state of anoxia (a partial reduction of oxygen to the brain) that results from asphyxial behavior. By reducing the amount of oxygen to their brain, they induce a semihallucinogenic and euphoric state.

The practice likely provides some form of reinforcement; otherwise, it would not likely be repeated. It is assumed that the decreased availability of oxygen leads to lightheadedness, which when coinciding with orgasm is subjectively felt to result in an enhancement of the sexual feelings. While there are clearly fantasy factors operating in the behavior, actually dying as a result of the practice is usually not part of the fantasy scenario, although that has occurred.

Furthermore, a significant number of Internet websites are dedicated to a variety of consensual sexual asphyxia-related activities, from social clubs to the dissemination of pornography. Masochism appears to be a persistent, integral part of the fantasy throughout. Those who enjoy these practices achieve sexual arousal and gratification from the physical act of choking, the psychological component of degradation and humiliation that is associated with harming oneself, as well as the element of actual danger that is involved.

Masochistic and danger-related fantasy behavior, often found in the form of props and pornography, are evidence of development and refinement of autoerotic fantasy over a period of time. Such evidence would tend to suggest that a given incident is not at all isolated. Fantasy-oriented behavior can include, but is by no means limited to, the following:

- The use of pornographic material during asphyxiation.
- The repeated use of special fantasy items and objects.
- The repeated use of a special location for the asphyxial ritual.
- The use of bondage-related devices and/or complex ligature arrangements.
- In the case of males, the use of female undergarments, including cross-dressing behavior (cross-dressing during autoerotic behavior may be suggestive of transvestitism, but it has most often been found to be employed for its masochistic value during the event).

Figure 1 Note wear patterns on the wooden beam in the garage from the attached rope, evidencing a desire for privacy and prior autoerotic activity (see the section 'Death Scene Characteristics').

Figure 2 Note the vibrator on the ground, partially exposed genitals, and the evidence of crossdressing (see the section 'Death Scene Characteristics').

Atypical Autoerotic Deaths

Nonasphyxial *autoerotic deaths* are often referred to as atypical *autoerotic deaths* because they involve sexual self-stimulation by means other than asphyxia. Recall that sexual asphyxia is the leading cause of autoerotic fatality.

An atypical autoerotic death can include all manners and forms of dangerous behaviors that are intended to increase sexual gratification, either physically or psychologically. Such behavior includes things such as self-torture/mutilation; insertion of foreign objects in the mouth, penis, vagina, and rectum; extreme, restrictive bondage; the use of electricity; use of fire (self-immolation); the use of water (self-immersion); and the use of dangerous toxins, drugs, and chemicals.

One example could be an individual who used a great deal of cocaine while watching a pornographic video and, while masturbating, died of a heart attack. Another example could be an individual who repeatedly inserted a large, pointed carrot into their rectum, causing a bowel perforation that led to an infection, and then death. Still another example could be an individual who attached electrodes to the anus while masturbating and died as the result of cardiac fibrillation. A final example could be an individual who repeatedly immersed himself/herself in bathtub water, and then accidentally bumped the head and drowned. In that case, a determination of autoerotic aquaeroticism would be possible if there were evidence of masturbation at the time of death, and a diary written by the victim detailing the heights of sexual pleasure achieved during aquaerotic behavior in the past.

Death Scene Characteristics

The identification of an autoerotic death scene requires deliberate and informed crime scene investigation and reconstruction efforts. *Crime scene investigation* includes crime scene examination and documentation, laboratory analysis of physical evidence, scientific interpretation of results, and scientific reconstruction efforts. *Reconstruction* refers simply to the determination of the actions and events surrounding the commission of a crime.

With any death that occurs in association with sexual activity, it is important to establish the presence of key death scene characteristics before it can be appropriately classified as an *autoerotic death*. In doing so, death investigators can hope to differentiate autoerotic death scenes from other similar types of death scenes such as suicides and sexual homicides.

The particular death scene characteristics discussed in this section are often ignored or overlooked entirely by investigators. The two main reasons for this are the general lack of knowledge about the nature of autoerotic behavior, and the fact that autoerotic fatalities often share common death scene characteristics with both suicides and sexual homicides.

There are typically 12 general behavioral characteristics that investigators can look for to help them identify autoerotic death scenes. It is not necessary for all of the behavioral characteristics listed to be present for a determination of autoerotic fatality. These 12 items are not used as an absolute, inflexible checklist. These behavioral characteristics, instead, are intended to be a guide that helps investigators identify various

forms of autoerotic behavior within a crime scene. The search for these characteristics is the basis for questions that death investigators consider when determining whether or not an autoerotic fatality occurred (**Figures 1 and 2**):

1. *Location.* In autoerotic deaths, the location is likely to be a secluded area with a reasonable expectation of privacy (e.g., a locked bedroom, bathroom, basement, attic, garage, workshop, motel room, or wooded area).
2. *Body position.* In asphyxial hanging deaths, the victim's body may be partially supported by the ground, or the victim may even appear to have simply been able to stand up to avoid strangulation.
3. *High-risk elements.* These are items that are brought into the autoerotic activity to enhance physical or psychological pleasure. They include anything that is potentially harmful or reduces judgment, such as drugs, alcohol, or weapons. These elements increase the risk of autoerotic death.
4. *Self-rescue mechanism.* This is any provision that allows the victim to voluntarily stop the high-risk element's effect (e.g., literature dealing with escape mechanisms, a slip-knot in a ligature around the victim's neck, the freedom to punch a hole in a plastic bag sealed over the victim's face, a remote safety button on a power hydraulic within or near the victim's reach, keys for locks, or the ability to simply stand up and avoid asphyxiation altogether).
5. *Bondage.* This refers to the use of special materials or devices that physically restrain the victim (e.g., handcuffs, leather harnesses, wrist manacles, elaborate ligature configuration). These items have psychological/fantasy significance to the victim. The presence of this characteristic can lead investigators to believe that a death was homicidal when it was not. In cases of autoerotic death, it is important to establish that the victim could have placed the restraints on himself or herself, without assistance. (Literature dealing with bondage may be found at the scene or investigation may reveal that such literature was available to the deceased.)
6. *Masochistic behavior.* This refers to inflicting psychological (humiliation) or physical pain upon sexual areas of the body, or other body parts. It is important to look not only for indicators of current use but also for healed injuries suggesting a history of such behavior, when appropriate (e.g., sadomasochistic literature, spreader bar between the ankles, genital restraints, ball-gag, nipple clips, cross-dressing, suspension).
7. *Clothing.* The victim may be dressed in fetishistic attire or in one or more articles of female clothing. However, cross-dressing or fetishistic attire may be absent. Clothing is not always a useful indicator in cases of autoerotic death. It is possible for victims of autoerotic fatalities to be fully dressed, nude, or in a state of partial undress.
8. *Protective measures.* The victim often will not want injuries sustained during regularly occurring autoerotic behaviors to be visible to others. Injuries may be inflicted only to areas that are covered by clothing, or the victims may place soft, protective material between their skin and restraining devices or ligatures to prevent abrasions and bruising (e.g., a towel may be placed around the victim's neck beneath a

hanging ligature, or wrist restraints may be placed over the victim's clothing, etc.).

9. *Sexual paraphernalia and props.* These are items found on or near the victim that assist in sexual fantasy (vibrators, dildos, mirrors, erotica, diaries, photos, films, female undergarments, method for recording the event (an audio-tape recorder, video camera, etc.)).
10. *Masturbatory activity.* The absence of sperm or semen at the scene does not rule out autoerotic death. The victim may or may not have been manually masturbating at the time of death. Evidence of masturbation strongly supports a determination of autoerotic death, however, and may be suggested by the presence of sperm or semen, tissues, towels, and lubricant on hands and sexual areas. Sexual devices may be present.
11. *Evidence of prior autoerotic activity.* This includes evidence of behavior similar to that found at the scene that predates the fatality (permanently affixed protective padding, plastic bags with repaired 'escape' holes, pornography from many different dates, a large collection of erotica, complex high-risk elements (very complex ligature configurations), complex escape mechanisms, healed injuries, grooves worn in a beam from repeated ligature placement, home-made videotape of prior autoerotic activity, witness accounts of prior autoerotic behavior, etc.). However, the event could be the first (and fatal) time the individual attempted such behavior. Additionally, the practitioner may not be at the usual location where he or she practices the behavior. In this event, while the asphyxia is a repeated practice, the location would not indicate that. For example, the victim could be found hanging in a hotel where he or she happened to be staying.
12. *No apparent suicidal intent.* The victim had plans for future events (e.g., the victim made plans to see close friends or to go on a trip in the near future). Absence of a suicide note is not necessarily an indication of an autoerotic event. If one is present, it must be determined that it was written around the time of death and is not a prop (part of a victim's masochistic fantasy). Other indicators that the victim did not commit suicide are that the victim had no history of depression, had recently paid monthly bills, and had spoken to friends of looking forward to a specific event.

While the prior is a list of possible elements, the following death scene findings are necessary to determine that a death is due to autoerotic asphyxia:

1. There is an expectation of privacy.
2. There is no convincing evidence of suicidal intent.
3. There is no evidence of another actor at the scene.
4. There is an apparatus to induce hypoxia.
5. The apparatus includes an escape mechanism, even if it is as simple as standing up.
6. The victim could have placed any bindings found.

Confounding influences on death scene findings include the friends and family of the victim. When friends or family members discover a loved one who has died from autoerotic asphyxia, their first impulse may be to sanitize the scene. They may remove and dispose of embarrassing items

(pornography, articles of female clothing, and sexual devices) and generally may act to preserve a loved one's dignity before notifying authorities.

Male Versus Female Practice

Historically, the literature has reflected a belief that autoerotic asphyxia is an adolescent male activity and that female devotees of the practice are either extremely rare or nonexistent. Several modern papers have alerted the forensic community to the fact that female autoerotic asphyxia is not as rare as believed and may be more problematic than male autoerotic asphyxia in sorting out the behavior from a sexual homicide or a suicide. Most recently, a 2006 study by Sauvageau and Racette found that female deaths resulting from autoerotic practice represent 4.6% of published cases. Regardless of the number of known cases, which may be underreported due to misidentification, the reality of female practice must be acknowledged and considered when developing case theory and reconstructing events.

The autoerotic death scenes of males tend to be quite different from the autoerotic death scenes of females. In male and female cases alike, the occurrence of autoerotic behavior has been found to be both secretive and repetitive. It has been found, however, that male victims tend to use a far greater range of elaborate devices and props during autoerotic behavior. These props are often designed to cause real or simulated pain. There is also a greater occurrence of cross-dressing and use of pornographic material.

Female victims, on the other hand, tend to be found naked, often using only a single device, with no excessive or elaborate apparatus or props. It has been repeatedly suggested that these death scene differences may account for a high level of underreporting and/or mislabeling of female autoerotic deaths. This is especially true when female victims of autoerotic fatalities are deeply involved with self-binding and other sadomasochistic behavior. This scenario can readily appear to investigators as a sexual homicide, perhaps the work of a sexual predator.

Other factors that tend to influence the characteristics found at an autoerotic death scene include the friends and family of the victim. When friends or family members discover a loved one who has been the victim of an autoerotic fatality, very often their first impulse is to clean up the scene. They remove and dispose of potentially embarrassing items (i.e., pornography, articles of female clothing, sexual devices), and generally act to preserve their loved one's dignity before notifying authorities. This is not criminal behavior done with criminal intent, and should not be treated as such. However, investigators must be aware that this type of intervention can and does happen, and they must anticipate dealing with it.

Psychological Autopsy

An important part of any medicolegal investigation into a death that occurs in association with sexual activity is the performance of what is referred to as a *psychological autopsy*.

A psychological autopsy is a term that refers to the process that death investigators and mental health experts use, in collaboration, to determine the state of mind of a person before they died.

The question that most commonly arises in cases involving a person who was alone at the time of death is whether or not the death was an accident or a suicide. It is believed that by making a very thorough examination of the victim's lifestyle and history (victimology), a more accurate determination can be made as to whether a death was an accident or a suicide. The question is not always answerable, but it most certainly cannot be answered without detailed information about both the death scene and the victim's history.

There are three major areas of investigative consideration when performing a psychological autopsy: wound pattern analysis, victim state of mind, and victim mental health history.

To evaluate wound patterns on the victim, a complete analysis is required. That means examining the injuries on the crime scene (in the environment that they were created in) and at autopsy (after they have been cleaned up) when possible. This also means, at the very least, making an examination of all documentation relating to the crime scene and the autopsy (sketches, photos, videos, reports, notes, etc.). Key questions that are asked of the wounds include whether or not there are hesitation marks, whether or not the deceased could have caused the injuries, where any weapons that were used were found, and the precise causes of death.

To evaluate the victim's state of mind prior to death, a complete background study of the victim's history and personality (victimology) is required. This includes conducting extensive interviews of the victim's friends and family, including close personal friends and any current or past intimates. Death investigators look for any of the classic warning signs of suicidal behavior. These warnings signs include giving away possessions, sudden cheerfulness or emotional calm after a prolonged depression, speaking of life in the past tense, social isolation, extreme changes in regular habits or activities, recent stressful events, an accumulation of stressful events, or recent deaths of friends and/or family. If there is a suicide note, this should be analyzed and compared to a sample of the victim's handwriting by a questioned document examiner. If a note is not found, handwriting samples should be taken anyway in case a note is found later. If a note is determined to have originated from the victim, then the contents of the note may reveal their state of mind and possible motives for their behavior.

To evaluate a victim's mental health history, a full and complete analysis must be made of their medical and mental health interactions. This means taking into account whether or not the victim was or had been under any professional care;

whether or not they were on any medication; and whether or not they had attempted suicide in the past.

These types of intensive background inquiries of the victim by law enforcement, or medicolegal death investigators, are not routinely conducted in sexual fatalities of any type (including sexual homicides). As a result, many autoerotic deaths are unreported or mislabeled as homicidal, suicidal, or undetermined deaths. Until such time as every scene investigator is educated regarding the true nature and form of autoerotic death, and the importance of reconstruction combined with victim history, the variety and frequency of autoerotic death will remain unknown.

Glossary

Behavioral evidence analysis A comprehensive inductive method of crime scene analysis and criminal profiling involving the examination and interpretation of physical evidence, forensic victimology, and crime scene analysis for behavioral patterns and clusters that suggest offender characteristics of investigative or forensic relevance.

Crime scene analysis The analytical process of interpreting the specific features of a crime and related crime scenes.

Criminal investigative analysis Developed by the Federal Bureau of Investigation, an investigative process that

identifies the major personality and behavioral characteristics of the offender based on the crimes he or she has committed.

Criminal profiling Inferring the traits of individuals responsible for committing criminal acts.

Diagnostic evaluation Profiling opinions offered by medical and mental health professionals who rely on clinical experience to evaluate offender behavior, crime scenes, or victims.

Forensic victimology The scientific study of violent crime victims for the purposes of addressing investigative and forensic questions.

Criminal profiling refers to inferring the traits of individuals responsible for committing criminal acts. Professionals involved in the practice of criminal profiling have historically included a wide array of investigators, behavioral scientists, criminologists, and forensic scientists. Profiling methods tend to be either inductive/nomothetic (e.g., statistical, experiential, and predictive) or deductive/idiographic (e.g., logical, rational, and concrete). When applied to unsolved cases, these methods have been used to help identify criminals, narrow suspect lists, assist with case linkage, develop leads, and design investigative strategies. As will be shown, some profiling methods also have a long-standing forensic tradition.

Criminal profiling has been referred to, among less common terms, as *behavioral profiling*, *crime scene profiling*, *criminal personality profiling*, *offender profiling*, *psychological profiling*, *criminal investigative analysis (CIA)*, and, more recently, *investigative psychology*. Because of the variety of profilers, their respective methods, and their various levels of actual education on the subject, there remains a general lack of uniformity in the application of these terms across and within certain profiling communities. Consequently, some terms are used inconsistently and interchangeably. For our purposes, we will be using the general term *criminal profiling*.

The Early History of Criminal Profiling

Blood Libel

One of the first documented uses of criminal profiling in an official context involves the demonization of Jews. The origins are found in a report made by the anti-Semite scholar Apion to the Roman Emperor Caligula in CE 38. Apion felt the Jews of Alexandria, where he had studied, had too many rights and privileges. Apion, documented in the writings of Flavius Josephus (*Contra Apionem*, circa CE 90s), falsely reported to Caligula that the Jews were often responsible for the ritual killing and eating of Greeks as part of Passover.

Blood libel, the false accusation of ritual killing, is an early and persistent form of criminal profiling because it involves a predetermined set of crime-related characteristics used to infer and consequently accuse a particular suspect pool – namely the Jews. The general fact pattern used included one or more of the following elements:

- A young Christian male goes missing.
- A Jewish community is nearby.
- The child goes missing on or just prior to Passover.
- The body may have injuries that appear to be the result of a ritual.
- The body may have lost a great deal of blood or may simply appear so.

Given this fact pattern, the inference is then drawn that the Jewish community has effected a ritual abduction, torture, and murder. This fear-based inference is often fanned by preexisting anti-Semitic beliefs. As the term implies, the accusations are libelous – intentionally false and inflammatory. The blood libel is therefore not just one of the first uses of profiling; it is one of the earliest documented forms of false reporting. In various forms, blood libel remains a feature of anti-Semitic rhetoric to this day.

The Malleus Maleficarum

One of the first published texts that offered explicit instruction on the subject and practice of profiling criminal behavior is the *Malleus Maleficarum* (*The Witches' Hammer*). Two Dominican monks, Henry Kramer and James Sprenger, professors of theology from the Order of Friars Preachers, originally published this work around 1486. It was intended to provide rationales and guidelines for those involved with the Medieval Inquisition (namely the authors) to assist in the identification, prosecution, and punishment of witches.

According to the *Malleus Maleficarum*, witches and other criminals may be identified by specific circumstances, abilities,

and characteristics as defined by the experiences of both its authors in concert with their interpretation of the Bible. Witches were described primarily as women who:

- have a spot, scar, or birthmark, sometimes on the genitals and sometimes invisible to the Inquisitor's eye;
- live alone;
- keep pets (a demon in animal form known as a *familiar*)
- suffer the symptoms of mental illness (auditory or visual hallucinations, etc.);
- cultivate medicinal herbs;
- have no children.

The *Malleus Maleficarum* also explains that dead bodies will flow blood from their wounds when their murderer is near.

The Spanish Inquisition

The Spanish Inquisition was originally ordained by the Catholic Church to assist the Spanish government with the identification of *conversos*. These were primarily Muslims (Moors) and Jews (*marranos*) who had pretended to convert to Christianity but secretly continued to practice their former religion. To help true Catholics better inform on their heretical neighbors, criminal profiling was adopted as one of the tools of choice.

In 1487, Innocent VIII appointed Tomas de Torquemada, a Dominican priest and Queen Isabella's confessor, to be the first Grand Inquisitor of Spain. Torquemada's office established a profile of Jewish behavior to help Catholics inform on their neighbors based on a book written specifically for his office, titled *Censure and Confutation of the Talmud*. Adoption of this text by Torquemada rendered the Practices of Judaism itself (accurately described or not) an ad hoc profile to be used as behavioral evidence against the accused of 'secret Judaizing.'

North American Witch Trials

In North America, during the late 1600s, the Puritans used profiling methods to detect and prosecute those whom they believed to be witches. This took place first in Boston, Massachusetts, with the prosecution of Goodwife Ann Glover for witchcraft. This effort was lead by Reverend Cotton Mather, Puritan minister of the Old North Church in Boston. He determined that the 'washerwoman' Ann Glover evidenced at least the following characteristics consistent with being witch – a profile he developed once she had been arrested and he was able to examine her: she was a 'hag'; she was afflicted with the same symptoms as the children; she gave a blasphemous response when asked if she believed in God (she was Irish-Catholic, so any answer consistent with that faith would have been blasphemous to a Puritan reverend); she could not accurately recite the Lord's Prayer; and the children, whose symptoms had subsided with her incarceration, became ill again when in the presence of one of Goody Glover's female relatives. Rev. Mather also made certain that her body was examined for the witch's mark.

At her trial, Ann Glover refused to speak in anything but her native Irish tongue. Subsequently, Rev. Mather conveniently interpreted her refusal to renounce the Catholic faith as a

confession to witchcraft. She was shortly thereafter convicted and sentenced to death.

In 1689, Salem Village negotiated with and hired its new minister, Rev. Samuel Parris from Boston. The community eventually became unhappy with his ministerial abilities and stopped paying him on a regular basis. In October of 1691, the community failed to support a tax increase to pay for his salary and the firewood he would need to last through the winter. Worse, some vowed to drive him out of the community. As a consequence, Rev. Parris began preaching about a conspiracy in the Village – a conspiracy against the church and himself alike. He naturally attributed this to Satan taking hold of the community.

On 20 January 1692, 9-year-old Elizabeth Parris and 11-year-old Abigail Williams, her cousin and from the same home, began acting in a fashion quite similar to the Goodwin children in Boston only 4 years previously. Eventually, other young girls in Salem Village began acting similarly. With talk of witchcraft already in the air, Dr. William Griggs arrived in mid-February to examine all of the afflicted girls. Finding nothing physically wrong with them, he concluded that the cause was supernatural.

Before the Salem Witch Trials came to an end, 20 people had been executed (14 women and 6 men), at least five people had died in prison, and more than 150 had been jailed. Most of those executed were hanged, but one man was actually crushed beneath rocks. The evidence against the accused in each case included the conclusion that they fit a particular profile – that of a witch.

A Modern History of Criminal Profiling

Modern criminal profiling methods owe themselves to a diverse history, grounded in the study of crime and criminal behavior (criminology), the study of mental health and illness (psychology and psychiatry), and the examination and interpretation of physical evidence (the forensic sciences). In its many forms, it has always involved the inference of criminal characteristics for investigative and forensic purposes.

Criminologists

Integral to criminal profiling has been both understanding the origins of crime and classifying criminal behavior. This falls under the banner of *criminology*, which is the study of crime, criminals, and criminal behavior. Two types of criminologists have intersected criminal profiling theory more than the rest: those who study the physical characteristics of criminals in order to make inferences about criminal character, and those who are concerned with applied criminal investigation.

The renowned Italian physician Cesare Lombroso is generally thought to have been one of the first criminologists to attempt to formally classify criminals for statistical comparison. In 1876, Lombroso published his book, *The Criminal Man*. By comparing information about similar offenders, such as race, age, sex, physical characteristics, education, and geographic region, Lombroso reasoned, the origins and motivations of criminal behavior could be better understood and subsequently predicted.

Lombroso studied 383 Italian prisoners. His evolutionary and anthropological theories about the origins of criminal

behavior suggested that, based on his research, there were three major types of criminals:

Born criminals: These were degenerate, primitive offenders who were lower evolutionary reversions in terms of their physical characteristics.

Insane criminals: These were offenders who suffered from mental or physical illnesses and deficiencies.

Criminaloids: These were a large general class of offenders without specific characteristics. They were not afflicted by recognizable mental defects, but their mental and emotional makeup predisposed them to criminal behavior under certain circumstances. This classification has been compared to the diagnosis of psychopathic personality disorder that came later from the psychiatric community.

According to Lombroso's theory of criminal anthropology, there are 18 physical characteristics indicative of a born criminal, providing at least 5 or more are present. These include features such as defects and deviations of head, ear, or eye size and shape; asymmetry of the face; abnormal dentition; long arms; and extra toes or fingers. Basically, anything that looks abnormal or irregular. Lombroso's theory is evolutionary in nature, suggesting that criminals represented a reversion to a more atavistic (apelike) human state. Noncriminals, of course, were thought to be more evolved and therefore less apelike. Lombroso felt that, based on his research, he could recognize those physical features that he had correlated with criminality. Many criminologists since Lombroso have made similar attempts to classify and predict criminality based on intelligence, race, heredity, poverty, and other biological or environmental factors.

The Austrian Jurist Hans Gross was more comprehensive in his understanding and application of criminal profiling to investigative matters. In 1893, Dr. Gross finished writing his seminal work, *Handbuch für Untersuchungsrichter, als System der Kriminalistik* (aka *Criminal Investigation: A Practical Textbook for Magistrates, Police Officers, and Lawyers*). This was a landmark publication in which Dr. Gross proclaimed the virtues of science against intuition and superstition. Arguably a founding father of modern criminal profiling, Dr. Gross wrote about the importance of carefully studying offender behavior. In *Criminal Investigation*, for example, he offers various methods for profiling the behavior of murderers, arsonists, thieves, counterfeiters, and females falsely reporting rape, to mention just a few. In his other well-known work, *Criminal Psychology*, he shows the same underlying propensity toward the necessity of criminal profiling, writing:

Is it not known that every deed is an outcome of the total character of the doer? Is it not considered that deed and character are correlative concepts, and that the character by means of which the deed is to be established cannot be inferred from the deed alone?

His publications outline a systematic approach to physical evidence examination, crime reconstruction, psychological assessment, and criminal profiling that remains relevant to criminal profiling even to this day.

Forensic Scientists

The practice of criminal profiling by forensic scientists has a long history. The first documented instance occurred more

than 100 years ago. During the Whitechapel (aka Jack the Ripper) murders in Great Britain in 1888, Dr. George B. Phillips, the divisional police surgeon (the equivalent of a forensic pathologist), engaged in a rather direct method of inferring criminal characteristics. He observed wound patterns and from these inferred offender knowledge and skill. For example, Dr. Phillips noted that injuries to one of the Whitechapel victims, Annie Chapman, indicated what he felt was evidence of professional skill and knowledge in their execution. In particular, he was referring to the postmortem removal of some of Annie Chapman's organs and what he felt was the cleanliness and preciseness of the incisions involved.

Further, as Dr. Wynne E. Baxter, coroner for the South Eastern District of Middlesex, stated to Dr. Phillips during a coroner's inquest into the death of Annie Chapman: "The object of the inquiry is not only to ascertain the cause of death, but the means by which it occurred. Any mutilation which took place afterwards may suggest the character of the man who did it." Behavior, they understood, was evidence suggestive of personality characteristics. This approach generally agrees with the work of Dr. Gross mentioned previously, providing that from the deed the doer may be known.

The tradition of forensic pathologists offering similar profiling opinions and insights continues to this day. However, they are not the only forensic scientists to do so.

Dr. Paul L. Kirk (1902–70), a professor of biochemistry and later forensic science at the University of California at Berkeley, is regarded by many as the father of modern forensic science. In 1953, subsequent to his work on the Manhattan Project during World War II, Dr. Kirk published the first edition of his seminal forensic textbook, *Crime Investigation*, a treatise on criminal investigation, crime reconstruction, and forensic examination that endures to this day as a foundational industry standard with few equals.

Dr. Kirk viewed criminal profiling as the natural outcome of physical evidence examination, and a vital aid to the investigative process. He explained that an examination of the physical evidence could allow forensic scientists to infer not only the clothing that an offender was wearing when they committed the crime but other physical characteristics as well (e.g., hair color, stature, and strength). He also argued that it was, in some cases, possible to infer the offender's occupation or background from the criminal choices made and the skill that was evident.

Subsequent to the published works of Dr. Paul Kirk, modern forensic science texts continue to acknowledge the important role that physical evidence examination and crime reconstruction can play in criminal profiling, suspect development, and suspect exclusion.

Behavioral Scientists

Psychiatry is the branch of medicine that deals with the diagnosis and treatment of mental disorders. A forensic psychiatrist (historically referred to as an alienist) is a psychiatrist who specializes in the legal aspects of mental illness. The psychiatrist is trained to elicit information specific to mental disorders through face-to-face clinical interviews, a thorough examination of individual history, and the use of tested and validated personality measures. Historically, psychiatrists

have infrequently applied their expertise to investigative matters, but they regularly apply it to legal (aka forensic) questions.

One of the earliest documented cases of forensic psychiatry intersecting with criminal profiling is that of Mendel Beilis, arrested in 1911 by the Kiev Secret Police for the ritual murder of a Christian boy. Mr. Beilis was jailed for 2 years while prosecutors built their case, all the while concealing exculpatory evidence. Criminal profiling was used at his trial in the form of expert testimony from Dr. Ivan Sikorsky, a forensic psychiatrist and professor at Kiev University. Dr. Sikorsky opined on the issue of Beilis' motive, stating that it was racial revenge. He based this forensic opinion on his comparison of the case facts to other similar cases. It fit what he believed to be a profile of ritual Christian murder. The jury was unconvinced, and Mr. Beilis was ultimately acquitted in 1913.

In the United States, the work of Dr. James A. Brussel of New York is considered by many to have advanced the cause of criminal profiling significantly. Dr. Brussel's method included the diagnosis of an unknown offender's mental disorders from behaviors evident at the crime scene. He would infer the characteristics of an unknown offender, in part, by comparing the criminal behavior to his own experiences with the behavior of patients who shared similar disorders. Dr. Brussel also subscribed to the opinion that certain mental illnesses were associated with certain physical builds, not unlike the theories of criminologists a century before. As a result, an unknown offender's likely physical characteristics were included in Dr. Brussel's profiles of unsolved cases.

During the 1940s and 1950s, a 'Mad Bomber' terrorized the city of New York.

He set off at least 37 bombs in train stations and theaters all over the city. Dr. Brussel was asked to analyze the case and he did so, though no written profile was provided. On 25 December 1956, the *New York Times* carried a story containing some of Dr. Brussel's predictions about the bomber (e.g., male; knowledge of metalworking, pipefitting, and electricity; had suffered some grave injustice by Con Ed, which had rendered him chronically ill; self-centered; middle-aged; possibly a virgin; Catholic; suffered from paranoia). It did not contain a prediction about wearing a double-breasted suit, though he is alleged to have told investigators that their suspect would be arrested wearing one.

When the police finally identified and arrested George Metesky for the bombings in 1957, Dr. Brussel's profile was determined to be generally but not completely accurate. Contrary to popular belief, Metesky was arrested wearing faded pajamas, not a double-breasted suit. He was, however, single and living with his two unmarried sisters. He was also allowed to change before being taken into custody, and that is when he put on the infamous double-breasted suit – a very common manner of dress at the time.

In the tradition of Dr. Brussel and similar professionals that followed, forensic psychiatrists, forensic psychologists, and other behavioral scientists are commonly thought to be associated with criminal profiling. In reality, despite endless film and television depictions, few forensic behavioral scientists are involved with the investigation of unknown offenders. Rather, clinicians most commonly provide mental health assessments for known offenders already in custody.

The Federal Bureau of Investigation

During the 1960s, an American police enforcement officer named Howard Teten began to develop his own approach to criminal profiling while working for the San Leandro Police Department in California. Teten studied under Dr. Paul Kirk, the internationally renowned criminalist, Dr. Breyfocal, the San Francisco medical examiner, and Dr. Douglas Kelly, a psychiatrist noted for his work in the Nuremberg war trials. These were his instructors in the School of Criminology, at the University of California, Berkeley, during the late 1950s. He also sought out and spent hours discussing cases with Dr. James Brussels, to develop his appreciation of the mental health perspective.

Later in his career, as a special agent (SA) for the Federal Bureau of Investigation (FBI), Teten initiated a criminal profiling program. He taught criminal-profiling techniques as an investigative aid, to be used in conjunction with other investigative tools. His first profiling course was called applied criminology, taught to the FBI National Academy in 1970. Later that same year, SA Teten rendered his first actual profile as an FBI agent in Amarillo, Texas. SA Teten also teamed with SA Pat Mullany, then assigned to the New York Division of the FBI, to teach abnormal psychology as it applies to criminal profiling.

In 1972, the FBI's Behavioral Science Unit (BSU) was formed. SAs Teten and Mullany were assigned to it and other agents were added. Made world famous by sensational true crime memoirs from retired BSU profilers such as John Douglas and Robert Ressler in the early to mid-1990s, the BSU has undergone numerous changes with respect to personnel, structure, and function over the years.

At the turn of this past century, a significant shift occurred among the profilers at the FBI, manifesting a rift between internal cultures and agendas. Traditionally, the BSU had maintained what was referred to internally as a 'three-legged stool' model: conducting research; providing education and training within the law enforcement community; and providing case consultations to support the efforts of police investigations. However, the model began to change when Stephen Band, a Ph.D. in counseling psychology, took over the unit in 1998. Under his administration, the cultural rift in the BSU between those who consulted on cases and those who performed teaching and research worsened. The two groups ultimately separated: one aligned with law enforcement investigators as the newly formed Behavioral Analysis Unit (BAU), and the other comprised Ph.D. educated behavioral scientists (BSU).

The BAU was created in 2000 as part of the BSU, intended to be subordinate to Dr. Band. The BAU consults on law enforcement cases, and the BSU conducts research and provides training. However, the BAU eventually removed itself physically from the FBI Academy in Quantico and began working from an off-site office location. This made real supervision impossible and rendered the BAU essentially autonomous. Dr. Band subsequently resigned as director of the BSU in 2005. The state of FBI profiling is currently unclear, as many of its major practitioners have retired into private practice.

The Academy of Behavioral Profiling

Today's profiling community is made up of professionals and nonprofessionals from a variety of backgrounds. At the

professional forefront is the *Academy of Behavioral Profiling (ABP)*, founded in March 1999. The ABP is the first international, independent, multidisciplinary professional organization for those who practice or who are studying profiling. It has a student member section; an affiliate member section for the interested, nonprofiling professional; and four full member sections (behavioral, criminology, investigative, and forensic).

The ABP has developed firm practice standards and ethical guidelines, which the membership agrees to follow under penalty of various levels of sanction. More recently, it has developed and deployed the Profiling General Knowledge Exam for those seeking to become full members. The goal of the organization is to provide structure and support for those diverse professionals actively involved in profiling work, as well as to allow members to advance within that structure based solely on their knowledge and the quality of their work.

Regardless of who is involved and regardless of the professional outlook, criminal profiling still is not typically a career in itself – although there are individuals who have made it so. Rather, it is a multidisciplinary skill that is nurtured and developed once one has become proficient in other requisite disciplines.

The Goals of Criminal Profiling

The goals of criminal profiling depend on the context. The two most common contexts are *investigative* and *forensic*. *Investigative* contexts are those that exist before a suspect has been identified. These include consultations or examinations for law enforcement or other investigators seeking to establish the facts of a case and identify suspects. *Forensic* contexts are those involving a defendant that is being tried in civil or criminal court. These include consultations or examinations for civil and criminal attorneys.

Investigative goals include the following:

- Evaluating the nature and value of available forensic and behavioral evidence in a particular crime or series of related crimes;
- Reducing the viable suspect pool;
- Prioritizing the investigation into remaining suspects;
- Linkage of potentially related crimes by identifying crime scene indicators and behavior patterns (i.e., modus operandi and signature);
- Assessment of the potential for escalation of nuisance criminal behavior to more serious or more violent crimes (i.e., harassment, stalking, voyeurism);
- Providing investigatively relevant leads and strategies;
- Helping keep the overall investigation on track by offering fresh and unbiased insights;
- Developing communication, interview, or interrogation strategies for dealing with suspects.

Forensic goals include the following:

- Evaluating the nature and value of forensic and behavioral evidence to a particular crime or series of related crimes;
- Developing insight into offender motive and intent before, during, and after the commission of a crime (i.e., levels of planning, evidence of remorse, precautionary acts, etc.);

- Linkage of potentially related crimes by identifying similarities in crime scene indicators and behavior patterns (e.g., victimology, modus operandi, and signature).

It is generally agreed that profiling alone should not be used to implicate a particular individual for a particular crime, given the known limits of behavioral evidence. Rather, a criminal profiler should serve to educate investigators, attorneys, judges, and juries regarding the state of the behavioral evidence, what it means, and what it does not. Depending on the legal jurisdiction, a criminal profiler is likely to be limited with respect to their actual admissible testimony. In some cases, such as those involving FBI methodology, courtroom testimony from profilers has been excluded entirely due to an absence of reliability.

Methods of Criminal Profiling

There are essentially three primary methods of criminal profiling in wide practice today: diagnostic evaluations (DEs), CIA, and behavioral evidence analysis (BEA).

The DE and CIA methods may be described as *inductive* and *nomothetic*. This means that they involve abstract predictions about possible and unverified offender characteristics using group studies of similar crimes (or experience) to suggest an average offender type. Nomothetic profiles do not represent an actual offender who exists in the real world. They represent varying levels of theory and possibility.

BEA is more *deductive* and *idiographic*. This means that it requires establishing and examining the features of a specific case to form a concrete assessment regarding the characteristics of the offender responsible. It is based on the study of the case at hand, and seeks to establish actual behavioral evidence of offender characteristics as opposed to those that are merely likely or possible.

Diagnostic Evaluations

The term *diagnostic evaluation* does not refer to or represent a single profiling method or unified approach. It is instead a generic description of the services offered by medical and mental health professionals who rely on clinical experience when giving profiling opinions about offender behavior, crime scenes, or victims. Without a clear and identifiable process, profiles based on DEs are heavily idiosyncratic, relying to a large degree on the specific background of the clinical profiler. The clinician's education, training, and experience dictate the approach taken at a given point in time, with the profile being an outgrowth of their understanding of criminals and criminal behavior, flavored with his or her own take on personality and mental illness. DEs are done on an as-needed basis, usually as one part of a broad range of services being offered.

Two dangers presented by DE are role confusion and relevance. First, a clinician's profiling process should not revolve around, or focus on, treatment issues. That is, mental health professionals should not confuse their role as investigative advisors with their role as mental health diagnosticians. Second, those conducting DEs seldom have experience in law

enforcement, criminal investigations, or related areas. As a consequence, DE profiles can lack investigative relevance and utility.

Criminal Investigative Analysis

The FBI has developed the most commonly known method of criminal profiling. However, FBI profilers currently refer to themselves as criminal investigative analysts and their profiling method as CIA. CIA is defined by FBI practitioners as an investigative process that identifies the major personality and behavioral characteristics of the offender based on crime behavior.

The CIA method arose primarily from the FBI's Criminal Profiling Project, a study of 36 incarcerated offenders and their 118 respective victims conducted between 1979 and 1983. This study resulted in the FBI's organized/disorganized offender typology, still in wide use today. An *organized* crime scene is one with evidence of planning, where the victim is a targeted stranger, the crime scene reflects overall control, there are restraints used, and aggressive acts occur before death. This is used to suggest that the offender is organized with the crime scene being a reflection of the personality of an offender, meaning the offender will have average-to-above-average intelligence, will be socially competent, will prefer skilled work, will have a high birth order, will have a controlled mood during the crime, and may also use alcohol with the crime. Conversely, a *disorganized* crime scene shows spontaneity, where the victim or location is known, the crime scene is random and sloppy, there is sudden violence, minimal restraints are used, and there are sexual acts after death. This is used to suggest the personality of the offender, with a disorganized offender having below average intelligence, being socially inadequate, having a low birth order, having an anxious mood during the crime, and using minimal amounts of alcohol. Despite these discrete classifications, it is generally held that no offender will fit neatly into either category, with most offenders being somewhere between the two: these offenders are called 'mixed.'

CIA is ideally comprised of a number of steps or stages in which information about the crime is gathered and determinations are made about its relevance and meaning: (1) evaluation of the criminal act itself; (2) comprehensive evaluation of the specifics of the crime scene(s); (3) comprehensive analysis of the victim; (4) evaluation of preliminary police reports; (5) evaluation of the medical examiner's autopsy protocol; (6) development of profile with critical offender characteristics; (7) investigative suggestions predicated on the construction of the profile. This kind of analysis requires advanced investigative, forensic, and behavioral education to effect competently. However, most FBI profilers are investigators and not forensic scientists, or even behavioral scientists which has limited their ability to validate or advance their methodology, or to testify about their conclusions in court.

Apart from a lack of scientific advancement and development of CIA theory and methodology since its inception, another limiting factor is an overall lack of efficacy. According to Howard Teten, in an FBI study of 192 cases in which profiling was performed, 88 cases were solved. Of those 88 cases, the profile was determined to have helped with the identification of the suspect only 17% of the time. Subsequently, FBI profiles

are admonished to come with a disclaimer that limits use to investigative efforts, delineating the uncertainty of findings.

Behavioral Evidence Analysis

BEA is a comprehensive inductive method of crime scene analysis and criminal profiling formally developed in 1998. It involves the examination and interpretation of physical evidence, forensic victimology, and crime scene analysis. For the purposes of criminal profiling, the results of these individual examinations can be analyzed for behavioral patterns and clusters that suggest offender characteristics of investigative or forensic relevance. Conclusions in a BEA profile are ultimately based on critical thinking, the scientific method, and analytical logic.

Forensic analysis is the first step in BEA, and refers to the examination, testing, and interpretation of any and all available physical evidence. A thorough forensic analysis must be performed on the physical evidence to help reconstruct the behavioral evidence in a case before a BEA profile can be attempted. Without this behavior, there can be no profile.

The next step is a *forensic victimology*, the scientific study of violent crime victims for the purposes of addressing investigative and forensic questions. It involves outlining the victim's exposure to harm based on his or her lifestyle and circumstances, the events leading up to any injury, and the precise nature of any harm or loss suffered. Establishing victim characteristics and their choices can lead to inferences about offender fantasy, motive, modus operandi, knowledge, and skill.

Crime scene analysis is the analytical process of interpreting the specific features of a crime and related crime scenes. Potential crime scene characteristics that must be established or at least considered to include, among many others, method of approach, method of attack, method of control, location type, nature and sequence of sexual acts, materials used, evidence of skill or planning, any verbal activity, precautionary acts, contradictory acts, modus operandi, signature behavior, and the amount of time spent in the commission of the crime. Crime scene characteristics are interpreted from an integrated examination of the established behavioral evidence and victimology. Because they depend on physical evidence, and complete evidence is not always available, not all crime scene characteristics may be established in every case. This can limit any subsequent findings, and in some cases may even prevent meaningful profiling efforts.

The results of the forensic analysis, forensic victimology, and crime scene analysis are examined for behavioral patterns and clusters that suggest offender characteristics of investigative or forensic relevance. These are presented in written format with the basis for each offender characteristic found clearly outlined with supporting evidence and argumentation. When insufficient evidence exists to form opinions about the characteristics of the offender responsible, specific suggestions are provided to outline further investigative action that must be taken.

Successful use of BEA methodology requires significant education and training in the forensic and behavioral sciences, as well as a great deal of time spent examining the case at hand prior to rendering conclusions. It is, also, only as reliable as the information that is being relied upon.

Glossary

Electrodermal responses Changes in the electrical properties of the skin in response to external stimuli.

Peripheral blood flow The volume of the blood measured in a peripheral organ such as the finger.

Plethysmograph An instrument for detection and recording variations in the volume of the blood passing through a limb or finger.

Relative blood pressure Changes in the force exerted by the blood on the walls of the arteries.

Skin conductance Changes in the current that passes through two electrodes attached to the surface of the skin, when voltage is held constant.

Skin resistance Voltage variation between two electrodes attached to the surface of the skin when the current that passes through the electrodes is held constant.

Introduction

Lying in humans is commonplace and relevant to many areas in life. A successful deception may provide the deceiver with obvious advantages, while unmasking a lie may generate social and economic benefits to the lie catcher. This is especially true in criminal investigations where evidence is gathered from information elicited from suspects. Better understanding of lying behavior may therefore be useful in determining whether an individual is deceptive regarding a specific, usually criminal, event. Despite efforts to develop skills to detect deception based on verbal and nonverbal behaviors, research in social and cognitive psychology has demonstrated that even professional lie catchers such as judges, police interrogators, intelligence officers, psychiatrists, and polygraph experts unassisted by instrumentation rarely surpass 60% accuracy when detecting deceit, where 50% accuracy is expected by chance.

Early Attempts to Detect Deception

Human beings involved in the assessment of credibility have traditionally devoted attention to develop accurate methods of deception detection. Many ancient attempts to detect deception were based on magic and mysticism. Actually, all the ancient methods could be classified as trial by either, torture, combat, or ordeal.

In ancient Greece and Rome, torture was not used as punishment, but rather as a means of investigation and detection, to elicit a confession from a person presumed to be guilty. In ancient Greece, torture was reserved for slaves and for strangers and was not applied to free citizens. In contrast, torture was a widespread procedure in Rome that spared no one. The torture of individuals accused of treason or of other crimes against the state became an admitted principle of Roman law. Torture was also used on witnesses, and to confirm the testimony of slaves, when required.

Torture was also the foundation of the notorious Spanish inquisition, and was used to detect hidden crimes committed by the unfaithful. The presumption of guilt led to the use of

cruel methods to force the accused to confess, and few escaped the odds of being found guilty.

In the Medieval period, the determination of a person's truth and deception was referred to divine judgment, based on the belief that manifestation of God's support is evidence of an accused righteousness. One method used in the Medieval period to ascertain truth was trial by combat. In this method, the outcome of a battle between contestants determined who was truthful.

The ordeal is another method through which people relegate the task of determining guilt and innocence on a divine power, based on the belief that God protects the innocent and punishes the guilty. The literature refers to various types of ordeals (boiling water, cold water, fire, balance, rice chewing, and others).

Today, the ordeal of the red-hot iron is still practiced by Bedouin tribes. The suspect licks a gigantic heated spoon and if he does not burn his tongue, he is acquitted. Interestingly, many suspects are proclaimed innocent after the test. This can be explained by the trust of the truthful suspect in the process: The innocent suspect behaves normally, and the saliva on his tongue spares him the injury. The fear of the guilty suspect, on the other hand, reduces the activity of the salivary glands, and when the dry tongue touches the hot iron, it is immediately burned.

Over time, the injustice and fallibility of torture, combat, and trial by ordeal led to the abandonment of these methods. The prevalence of the scientific method encouraged the search for evidence-based methods to detect guilt.

Detecting Deception Using Behavioral Cues

A more systematic approach to the detection of lies assumes that the behavior of liars differs from the behavior of truth tellers, and therefore lying behavior can be identified by unique and objective behavioral cues of deception. Yet, studies analyzing lies of college students in laboratory settings (participants lied about personal opinions, about events they had experienced, and about mock crimes they had conducted)

show that reliable cues of deception are scarce. True, liars seem to be more tense than truth tellers, their pupils are more dilated, and they tend to raise the pitch of voice more than their truthful counterparts. There are also indications that liars talk for a shorter time and their statements are less detailed compared to truth tellers; truth tellers tend to correct themselves and admit not remembering, compared to liars. Unfortunately, these cues are not unique to deception and their validity is weak. To confound the matter, people hold incorrect beliefs about cues of deception. Incorrect cues, such as gaze aversion, an increase in speech disturbances (e.g., hesitations, more frequent pauses), and an increase in smiling and movements (of the trunk, hand/finger, and leg/foot) further affect lie detection accuracy.

The Myths of Hypnosis and Narcoanalysis

The search for methods to detect deception also gave rise to two myths concerning the potential contribution of hypnosis and narcoanalysis. There are two major views on hypnosis. One believes that hypnosis represent a special form of consciousness which permits access to hidden parts of the mind. The other major view explains hypnosis by social psychological mechanisms and suggests that the hypnotized individual is affected by the social situation. Both views agree that hypnosis has no truth-compelling capacity: The person under hypnosis retains control and is able to judge events, and therefore can lie.

Another myth involves truth serum testing. Narcoanalysis was first used in psychiatric proceedings to facilitate communication with emotionally disturbed patients. Drugs such as sodium amytal and sodium pentothal induced relaxation, ease, confidence, and a marked verbal release. It seemed as if the patient under the influence of the drug did not stop talking. The relief from inhibitions and the reduced self-censorship of speech triggered the idea that administration of these drugs would reveal an individual's hidden truth. However, it soon turned out that guilt-ridden people confessed under narcoanalysis to offenses they had imagined but had not committed, and others denied crimes despite objective signs indicated they were guilty.

Integrity Tests

Paper and pencil tests, and more recently computerized tests, were developed for use in preemployment screening and other selection purposes to predict employee thefts and other counterproductive behaviors in the workplace. Some are overt integrity tests that ask applicants about their attitudes toward theft and other dishonest activities, and about their own involvement in such behavior. Other tests disguise their aims and pose questions on dependability, conscientiousness, social conformity, trouble with authority, and hostility. Integrity tests assume that honest people will be honest in all situations, and dishonest people are consistent in showing dishonest behavior.

Integrity tests remain controversial for several reasons, including their effectiveness and the consequences of their use. The validity of these tests has been questioned. The tests are

designed to measure honesty, but it is argued that there is no such trait as honesty. The US Office of Technology Assessment reviewed the research on integrity tests and concluded that there is no scientific support for the claim that integrity tests can predict dishonest behavior. The report asserts that integrity tests are biased against applicants and produce a high rate of false positive errors (classifying an honest applicant as being dishonest). As a result, such misclassified applicants will suffer from a stigma and probably will be denied employment. Integrity tests have been further criticized for being vulnerable to faking, coaching, and retaking. In contrast, the American Psychological Association has expressed a more favorable view on integrity tests. In their report they suggested that properly documented integrity tests can predict a number of dishonest behaviors, and the validity of these tests is comparable to many other tests used in preemployment selection.

Although findings are inconclusive, the critical approach to integrity tests currently prevails. More experience and research are necessary to support a definite conclusion about the validity and application of integrity tests.

Detecting Deception from Verbal Content

Other methods developed to detect deception are based on the analysis of verbal content. An analysis is performed of the transcripts of suspects' statements containing detailed descriptions of what they did or what they saw. These methods assume that truthful statements differ from false ones in both content and quality. Several content analysis methods have been developed.

Statement Analysis

One method, which was developed for the assessment of child witnesses in sexual abuse cases, is known as 'statement validity analysis' (SVA). The SVA consists of two components: (1) a criteria-based content analysis (CBCA) that uses 19 criteria to identify qualitative and quantitative differences between truthful and untruthful reports; and (2) examination of other evidence in the case. It is believed, for example, that a detailed report containing an exact description of the place, a vivid description of people, and a step-by-step description of the events suggests that the statement reflects the truth. Research conducted to validate the SVA yielded positive results for three CBCA criteria: It was found that deceptive accounts contained fewer details and were rated as being less coherent than truthful reports. Dishonest suspects were also less likely than honest suspects to admit not remembering aspects of the event under consideration.

Reality Monitoring

Reality monitoring (RM) refers to the ability to distinguish real experiences from imagined events. It was suggested that memories of real events tend to contain more perceptual information (details concerning senses) and contextual information (spatial and temporal details) than false memories that contain more cognitive phrases than true memories.

RM rests on a well-established theoretical framework, and studies show an overall accuracy of about 75% in correct classification of truthful and deceptive statements. It was observed that the technique is equally accurate in detecting truths and lies. While promising, additional research is needed to gain more knowledge about the RM.

Scientific Content Analysis

Another method through which deception may be detected is the scientific content analysis (SCAN) technique. SCAN assumes that deceptive suspects will use more deviations in pronoun usage (such as replacing I with you) and will present long introductions or omit an introduction altogether. Deceivers will also use many unnecessary connectors, such as 'after I left,' and 'and then.' The SCAN appears to have intuitive merit, but no scientific evidence exists on its validity.

Lexical Diversity

Yet another verbal content analysis approach assumes that liars use different words than truth tellers and therefore a person's choice of words may reveal deception. This approach calculates type-token ratio (the number of distinct words in a statement (types) to the total number of words (tokens)) and proposes that a higher type-token ratio may indicate deception. This is explained by the cautious approach of deceptive suspects. In their efforts to conceal self-incriminating information, they phrase their statements at a higher level of lexical diversity. Further research is required to support the validity of this method.

Psychophysiological Detection of Deception

The Polygraph

When we speak about detection of deception, the first thing that comes to mind is the polygraph. The polygraph is a device that continuously measures and records physiological responses (such as respiration, sweating, and relative blood pressure) from an examinee who answers a series of questions. Changes in respiration are obtained from two pneumatic rubber tubes positioned around the thoracic area and abdomen. Hand sweating or skin resistance responses are obtained from two stainless-steel electrodes attached to the volar side of the index and fourth fingers of the examinee's hand. A small current is passed through the electrodes and the voltage between the electrodes that varies with skin resistance is computed. In experimental settings skin conductance is preferred over skin resistance. Here, the voltage is held constant and variations in the current flow are computed. Blood pressure is obtained from an inflated pressure cuff positioned around the upper portion of the examinee's contralateral arm (Figure 1). A measure that is used less frequently is peripheral blood flow obtained from a photoelectric plethysmograph placed on the examinee's finger.

After the examination the examiner scores the charts manually or analyzes the recordings using computerized algorithms. The analysis highlights inhibition of respiration,

Figure 1 The polygraph attachments.

Figure 2 Illustration of respiration, electrodermal, and cardiovascular patterns of recording on a chart.

electrodermal response amplitude, and changes in blood pressure and blood volume (Figure 2).

There are several polygraph examination methods. Two of them, the comparison question test (CQT) and the concealed information test (CIT), received more attention than others and are the focus of an ongoing controversy.

The Comparison Question Test

The CQT is the most common psychophysiological lie detection method. Basically, the CQT comprises three types of questions: (1) Relevant questions, which refer to the crime under investigation, using a 'Did you do it?' format (e.g., 'Did you break into Mr. Jones's store last Saturday?'). Relevant questions are typically answered 'no.' (2) Comparison questions, which refer to undesirable acts in the past pertaining to events that are similar to the crime under investigation but posed in a more generalized form (e.g., 'Between the ages of 12 and 16 did you ever take something valuable without permission?'). Comparison questions are formulated with the intention that the examinee retains some degree of self-doubt about the veracity of his 'no' answer. (3) Irrelevant questions, which focus on completely neutral issues to which the affirmative answer is a known truth (e.g., 'Are you sitting on a chair?'). Irrelevant

questions are intended to absorb the examinee's initial orienting response evoked by an opening question, and to allow rest periods between more emotionally charged questions. Typically, the entire question series is repeated three or four times.

The inference rule underlying the CQT is based on a comparison of the examinee's responses to the relevant and comparison questions. Deceptive individuals are expected to show more pronounced responses to relevant questions, whereas truthful individuals are expected to show greater responses to the comparison questions.

The CQT is convenient to use. Actually, all that is needed is a suspect who denies involvement in a crime and is willing to take the test. Practitioners love to use the CQT mainly because it allows them to best express their lie detection skills. The CQT is also highly controversial. The controversy revolves around the plausibility of its underlying rationale, potential contamination by background information, and other concerns related to countermeasures, privacy, standardization, and validity. In terms of validity, for example, the CQT has shown a tendency toward false positive errors (classifying innocent suspects as being deceptive) which poses a problem in the legal system where false positives are considered more grave than false negatives (classifying guilty suspects as truthful). Estimates of overall CQT validity vary, which makes it impossible to provide exact effectiveness statistics. All it can be said is that the CQT has some discriminative value.

Despite the heated controversy regarding its validity and theoretical foundations the CQT is the preferred method in most of the world. Currently, about six dozen countries use the CQT for deception detection. In the United States, where psychophysiological detection of deception was first introduced, the CQT remains the method of choice.

The Concealed Information Test

The CIT, which was formerly known as the Guilty Knowledge Test, is less controversial than the CQT yet has been adopted by field practitioners only in Japan. The CIT utilizes a series of multiple-choice questions, each having one critical alternative (e.g., a feature of the crime under investigation) and several neutral (control) alternatives, chosen so that an innocent suspect would not be able to discriminate them from the critical alternative. In the CIT, inferences are made by comparing the responses elicited by the critical item with the responses to irrelevant items. Concealment of crime-related information is inferred only if the examinee consistently provides greater responses to the critical item. This method provides adequate control against false positive outcomes: It is possible to reduce the likelihood that an innocent examinee might show consistently greater responsiveness to the correct alternative by chance by adding irrelevant items and by utilizing a greater number of CIT questions.

A meta-analysis conducted on laboratory studies indicates that the CIT is a highly valid method for distinguishing guilty from innocent participants. Under nearly optimal conditions (i.e., using a mock crime procedure, motivational instructions, deceptive verbal response to the critical items, and at least five CIT questions), the CIT generated an unusually high average effect size ($d=3.12$). However, real-life criminal investigation conditions typically differ drastically from experimental

conditions and are more often less than optimal. Two field studies were developed to examine the accuracy of the CIT in actual field practice. Using electrodermal responses as the sole index of concealment, a very high correct detection rate for innocent suspects was observed. However, a considerably lower correct detection rate for guilty suspects was reported. Results were explained by the inability of police interrogators to be sure that the guilty suspect noticed all critical details of the crime and remembered them at the time of the test. The small number of questions used in the two field studies (approximately two questions per test) may have contributed to the false positive error rate.

Countermeasure Attempts

An important issue related to polygraph testing in general and to the CQT and CIT in particular concerns the vulnerability of the test to attempts made by guilty suspects to distort their physiological responses.

Two major types of specific countermeasures are employed by guilty suspects that seek to manipulate polygraph outcomes: physical activities such as muscular movements, self-induced pain, or controlled respiration, and mental activities such as focusing on relaxing or exciting thoughts. The present evidence suggests that both types may be efficient in distorting electrodermal responses, in experimental situations where the conditions are optimal and participants receive information and training about the effective use of countermeasures. In real-life conditions, however, when the test is administered immediately after the interrogation, the suspect does not have sufficient time to prepare, and the countermeasures may not be effective. Furthermore, respiration and blood volume measures are more resistant to the effects of specific countermeasures. This may suggest that more weight should be given to these measures in the CIT.

Other Psychophysiological Measures

Event-Related Brain Potential

Another promising method for detecting deception and concealed information is the use of the P300 component of event-related brain potentials (ERPs). ERPs are measures of the brain's electrical activity, obtained from electrodes connected on the examinee's scalp. The P300 component of the ERP refers to a positive change in voltage of the peak that emerges at about 300 ms after presentation of a stimulus. The P300 signals special cognitive processing of recognized or infrequent stimulus and is therefore ideal for detecting concealed information. It has been shown that guilty examinees produce P300 responses to stimuli recognized as critical knowledge. Further, the short latency of the P300 response is likely to undermine the effectiveness of specific countermeasures.

Functional Magnetic Resonance Imaging

In the last decade, neuroimaging techniques have been developed to detect deception. One such method is functional magnetic resonance imaging (fMRI). Using this method, the analyst determines the precise anatomical location of brain

activation when the examinee is lying and when he is telling the truth. In fMRI studies, the examinee is instructed to lie to all questions and then to tell the truth. The brain activity obtained in the truthful and deceptive conditions are compared, and the brain regions critically involved in deception can be derived. The method is promising but it is not sufficiently mature for application in actual deception detection situations. One reason is that the brain regions that are active while lying vary across studies, and findings have not been replicated even with studies that use similar experimental procedures. Generally, the prefrontal cortex is more active when an individual is deceptive or conceals information than when truthful responses are given, but additional research is needed to provide a reliable and valid fMRI test for detecting deception.

Unobtrusive Detection of Deception

Methods for detecting deception of people who are entirely unaware of the interrogation may be very appealing. With such methods, there is no need to hook the suspect to a machine, and information may be gathered remotely. The use of covert methods may, however, raise ethical and legal concerns, including privacy and preexamination consent, which is currently required of polygraph examinees. The following are several covert methods for the detection of deception and concealed information.

Covert Respiration Measures in Polygraph Testing

Recent covert deception detection methods include two respiration measures using respiratory effort transducers hidden in the seat and in the back support of a polygraph examination chair. The transducers recorded changes in the pressure that inhaling and exhaling put on the seat and back support without the awareness of the suspect. Under experimental conditions the two covert measures were effective in detecting concealed information. It was suggested that such measures may be useful in reducing anxiety and combating countermeasures.

Analysis of Voice Stress

Several devices have been invented to detect emotional stress in the voice. The mechanical PSE (psychological stress evaluator) and its more recent computerized version have received more attention than others as tools for lie detection. The PSE purports to detect changes in the infrasonic frequency modulation that vary between 5 and 20 Hz. These modulations are controlled by the central nervous system and disappear during stress. The theoretical basis of the PSE has, however, been criticized as invalid, and experimental studies have failed to establish its validity. The use of voice stress analyzers was brought before the National Research Council, which was preparing a report on polygraphs and lie detection. The Council concluded that computer-based voice stress analyzers or similar voice measurement instruments had no scientific basis. Nonetheless, interest in the voice as a potential channel for the detection of deception remains, and new computerized voice analysis devices are introduced from time to time. The layered voice analysis (LVA) is such a recent method. The LVA

uses a computer program to analyze errors in the voice that are not audible to human ears. Research has not supported the validity of the LVA.

Thermal Imaging

Another potential method for unobtrusive detection of deception is thermal imaging or thermography, which is based on facial temperature changes related to blood circulation. Recent experimental results suggest that thermal image analysis may effectively discriminate between guilty and innocent individuals during the CIT. However, there is no sufficient scientific evidence to support the use of facial thermography in detecting deception. It seems that much additional research is needed to determine the facial thermography value in unobtrusive detection of deception.

Summary and Conclusion

Detecting deception has come a long way from early attempts based on divine intervention to recent computerized psychophysiological methods, yet the search for more accurate procedures and more refined indices continue because the available methods are less than optimal.

Most contemporary efforts to detect deception and reveal concealment of information are based on polygraph testing. CQT is the most popular method employed in the field, mainly due to its availability and ease of operation. It is also popular because it allows more discretion to operators and permits them to express their expertise. However, in view of a major controversy around the CQT's rationale, inference rule, and empirical validity, another method, the CIT, was developed. Due to its classical controlled experimental format, most scientific research conducted today is devoted to the CIT.

A recent trend in deception detection is the search for covert physiological measures that are less known to the public. Several measures shown to be efficient in lie detection and/or in unfolding concealed knowledge include heart rate (remotely recorded using laser Doppler vibrometry), eye blinks (monitored from simple video footage), and pupil size and eye movements (measured using covertly positioned eye-tracking devices). As until now all the tests were conducted in laboratory settings, additional work is needed to determine if and to what extent these measures can be applied to detect deception and/or concealed information in actual settings. Furthermore, additional thought must be devoted to the use of covert measures in correspondence with basic ethical principles.

Glossary

Bayes' factor The ratio of the odds in favor of a hypothesis given data divided by the odds of the hypothesis prior to considering the data. The Bayes' factor equals the likelihood ratio.

Bayes' rule An individual may start with a subjective probability (the 'prior') that expresses a degree of belief about a hypothesis. Bayes' rule gives a procedure for combining this prior with evidence to compute the 'posterior' probability, which expresses the investigator's or fact finder's belief about the hypothesis given the evidence. In its simplest form, Bayes' rule states that the posterior odds in favor of the hypothesis are the product of its prior odds and the likelihood ratio for the hypothesis.

Likelihood A measure of the degree to which data support a hypothesis about the process that produced the data. The likelihood for a hypothesis is proportional to the probability of observing the data assuming that the hypothesis is true.

Likelihood ratio The ratio of the likelihoods of two competing hypotheses. Numerically, it equals the ratio of the conditional probability of data given one hypothesis to the conditional probability of the data given the other hypothesis.

Odds The probability that an event will occur (or that a hypothesis is true) divided by the probability that it will not (or that the hypothesis is false). For example, if the chance of rain tomorrow is $2/3$, then the odds on rain are $(2/3)/(1/3) = 2/1$, or 2 to 1; the odds against rain are 1 to 2.

P-value The p -value is the probability of getting data as extreme as (or more extreme than) the observed data under the 'null hypothesis' that the data arise purely from random variation. A statistical hypothesis test asks whether the data are outside the range that reasonably would be expected under this null hypothesis. Large p -values are consistent with the null hypothesis; small p -values undermine this hypothesis. However, p itself does not give the probability that the null hypothesis is true.

Introduction

Natural and social scientists collect and interpret data, and they develop and apply theories about the phenomena that produce the data. Measurements of the 3° cosmic background microwave radiation, for example, permit inferences about the nature of the early universe, ruling out some theories and supporting others. Likewise, forensic scientists make measurements, interpret them, and evaluate certain theories in light of them. Their theories tend to be particular rather than general: This white powder contains D-cocaine; these grains of pollen originated from plants in this geographic area; these striations on a bullet resulted from this gun (or one remarkably like it); these bloody fingerprints were deposited by this finger (or one remarkably like it); and so on. Many theories in other fields of science, such as inferences about the features of the early universe, are also particular rather than universal.

Forensic science differs from all other branches of science, however, because forensic scientists perform one unusual set of tasks. They present and explain their findings not only to fellow scientists, but also to investigators, lawyers, and judges or juries. They must do so in a way that helps people who do not possess scientific expertise make practical decisions. Ultimately, the task of the forensic scientist is to supply accurate and useful information to legal investigators and decision makers. This article concerns the task of translating laboratory measurements into statements that will assist legal fact finders in evaluating hypotheses about the events that are relevant in legal disputes.

For concreteness, the discussion refers to the interpretation of trace evidence – primarily DNA and fingerprints – but the

analysis applies to a broad range of forensic evidence. The next section outlines a general, probabilistic perspective on moving from data to hypotheses. The final section examines common interpretive practices from this perspective and in light of the needs of the legal system.

A Framework for Inference

Measurements Are Not Necessarily True Values

Associating a trace with its source involves two logical steps: (1) ascertaining the similarities and differences between two samples and (2) assessing the significance of the measurements. The measurements pertain to properties of the material or mark – the refractive index of glass, the color of hair, the sizes of DNA fragments, the concentrations of elements, and so on. Let X be a variable (a scalar or a vector) whose possible values x depend on these properties. For instance, if X is the color of a hair fiber and the measurements are visual observations, then categories such as white, gray, blond, red, brown, and black are values x of X . A continuous variable such as a refractive index has an infinite number of possible values. An analyst comparing two items measures values m_1 for item 1 and m_2 for item 2. Because of inherent or other limitations in the measurement process, these values almost always differ from the true values. How should the analyst interpret m_1 and m_2 ? What can and should the analyst say in written reports or in courtroom testimony about the origin of the two samples in light of the measured values?

Likelihoods Indicate Relative Support

Statistically, the information from the measurement phase can be expressed in terms of likelihoods. Likelihoods are proportional to the conditional probabilities of the data given in different states of the world. They indicate the degree of support that the measurements lend to claims about these states. The underlying idea is that measurements that would arise more frequently or with a greater probability under one hypothesis than another support the former hypothesis more than the latter. For instance, looking out of a window and seeing that it is dark supports the hypothesis that it is midnight much more than it supports the hypothesis that it is midday. Darkness at noon can occur (during a total solar eclipse), but these events are rare, whereas darkness at midnight is common.

A little notation is helpful in spelling this out in the forensic context. If S is the hypothesis that the pair of samples originated from the same source, then the likelihood for S is (within an arbitrary multiplicative constant) just the conditional probability $P(m_1 \& m_2 | S)$. (Here, '|' means 'given' or 'conditioned on'.) Similarly, if D is the hypothesis that the pair came from different sources, then the likelihood for D is $P(m_1 \& m_2 | D)$ (multiplied by the same constant). The ratio of the two likelihoods is thus

$$LR_m = \frac{P(S; m_1 \& m_2)}{P(D; m_1 \& m_2)} = \frac{P(S | m_1 \& m_2)}{P(D | m_1 \& m_2)} \quad [1]$$

Note that when the data are equally probable under each hypothesis, they are of no value in deciding which competing hypothesis is true. In this situation, LR_m is 1, and the results of the forensic examination are inconclusive.

If the data are 100 times more probable when the samples come from the same source than from different ones, then the likelihood ratio for the hypotheses is $LR = 100$. The data support S 100 times more strongly than they support D .

Likelihood ratios of 10^{15} (and more) have been quoted for DNA evidence in the United States. These ratios are not conditioned strictly on the basis of the measurements m_1 and m_2 . The actual measurements are reflective fluorescence units as the DNA fragments flow past a detector. Software converts them into a graph (an electropherogram). Distinct peaks rising far enough above the level of background noise indicate alleles of different lengths. A good deal of interpretation already has taken place in deducing the allele lengths. Likewise, with friction ridge skin comparisons, deciding what features to compare and how similar the features are is an interpretative activity in the measurement phase.

The large DNA likelihood ratios apply to the inferred genotypes, not to the original measurements. To be clear about this, let g stand for the pair of genotypes inferred from the measurements m_1 and m_2 and write $LR_g = P(g | S) / P(g | D) = 10^{15}$. If the interpretation of the peaks is correct, then $LR_m = LR_g$, but even a small probability that the true genotypes are not those inferred from the electropherograms reduces the likelihood ratio (i.e., $LR_g < LR_m$).

Bayes' Rule Gives Probabilities of Hypotheses

With likelihood ratios like 10^{15} , DNA analysts sometimes report that the source of the known sample is the source of the

questioned sample. Fingerprint analysts also make such source attributions, although traditionally they have had no quantified likelihood ratios to quote and have relied instead on a difficult-to-validate theory of 'universal, general uniqueness' of all pairings of the unknown mark with all marks that could be derived from all possible reference samples on earth. A definite source attribution expresses the analyst's conviction that out of all the people or objects that conceivably might be the source of the questioned sample, only the one that generated the 'matching' known sample is a realistic possibility.

Source attribution can be overtly probabilistic. The 'probability of paternity' used in courts for the last 30 or 40 years is the best-known example. Suppose that only a small, degraded sample of DNA is available from the limited remains of a body that might be the child of two parents who reported a missing child. The likelihood ratio for the hypotheses of the child belonging to these parents versus a randomly selected set of parents, considering only the genotypes of the DNA samples from the remains and the two putative parents, might be 100. (To keep things simple, this overlooks the possibility that the remains are those of a child of one but not of both the putative parents.) To move to the probability of the hypothesis of parentage, however, Bayes' rule is needed. A simple version of the formula indicates the impact that the likelihood ratio of 100 would have on any set of prior odds for parentage. Letting S be the hypothesis that the remains are those of the offspring of the putative parents, G the genotypes of the trio, and N the nongenetic evidence about S and general background information, the formula states that

$$\begin{aligned} \text{Odds}(S | G \& N) &= LR \times \text{Odds}(S | N) \\ &= 100 \times \text{Odds}(S | N) \end{aligned} \quad [2]$$

Allowing the nongenetic information N to be implicit gives the more common, shorter formula

$$\text{Odds}(S | G) = LR \times \text{Odds}(S) \quad [3]$$

Thus, if the nongenetic evidence established prior odds of 1:10 (a probability of $1/11 = 0.09$), the reported genotypes (if accurately ascertained) would raise the odds to $100:10 = 10:1$ (probability $= 10/11 = 0.91$). Bayesian statisticians thus can describe the likelihood ratio as the ratio of the posterior odds to the prior odds ('Bayes' factor'). But one need not believe that it is justifiable to assign probabilities to hypotheses to take the narrower view that the likelihood ratio expresses the relative support that the evidence gives to one hypothesis over another.

Bayesian Decision Theory Selects Between Hypotheses

In principle, an analyst can reach a conclusion about the source hypotheses by selecting the one that maximizes the analyst's expected utility. For example, an analyst might feel 9 units of regret for declaring a common source when, in fact, the samples come from different sources (endorsing S when D is true); 1 unit of regret for endorsing D when S is true; and be unmoved (feel 0 units of regret or satisfaction) for correct decisions. If the analyst declares S , then the expected regret is $9 \times P(D | m_1 \& m_2)$; if the analyst declares D , the expected regret

is $1 \times P(S|m_1 \& m_2)$. Since $P(D|m_1 \& m_2) = 1 - P(S|m_1 \& m_2) = 1 - p$, the analyst minimizes expected regret by endorsing S whenever $9(1-p) < p$, that is, whenever $p > 9/10$. A risk-neutral analyst who is still more distressed by false identifications relative to false exclusions should not declare S unless the source probability crosses an even higher threshold.

Current Practices and Possible Improvements

The previous section sketched a framework for moving from measurements m_1 and m_2 on a pair of samples to statements about the implications of these measurements. The ideas shed light on how an analyst can and should present the findings.

Reporting an Exclusion, Match, or Inconclusive Result

Reports from examiners who compare samples based on training and experience normally begin with a statement about the degree to which the measurements on the samples agree. Phrases such as ‘match,’ ‘consistent with,’ ‘identical,’ ‘similar in all respects tested,’ and ‘cannot be excluded as the source of’ merely express a finding that the observed features in the two samples show a high degree of correspondence and no great differences (compared to what the examiner expects for marks from the same source). By themselves, these terms are relatively uninformative. The significance of the consistency can be high (as it usually is with fingerprints or DNA), moderate (with more common feature sets), or low or even unknown (as some commentators argue is the case for hair and bite marks).

When the observations do not correspond well, an examiner may testify to an ‘exclusion.’ An exclusion means that, according to the examiner’s knowledge base, the measurements are so different that they would almost never arise when the items have a common source, while the measurements could easily be this different when the items come from different sources. In other words, an exclusion means that the perceived likelihood ratio is close to 0.

Finally, a forensic analyst may decline to classify or characterize the pair of samples, as when a fingerprint examiner decides that a latent print is not even worth comparing (‘not suitable’) or a DNA analyst finds that the quality and quantity of the DNA is unacceptable. Or, the analyst may give it a try but then discover too little useful information to say more than ‘inconclusive.’

When the measurements lie on a continuous scale, as with the refractive index of glass, the nomenclature of ‘match’ versus ‘exclusion’ is artificial. A numerical likelihood ratio indicates the probative value of the degree of correspondence directly. There is no need for an intermediate step of forcing the continuous variable into discrete categories. Nonetheless, speaking of ‘matches’ or ‘inclusions’ and then describing their significance may be more familiar and comprehensible to judges or jurors. When this terminology is used, it is important to explain the intended meaning.

Reporting Random-Match Probabilities and Frequencies

The most common way of explaining the significance of a DNA match is to report a random-match probability (RMP) or estimated frequency in major population groups. Finding a match

in unusual traits obviously is more probative than a match for common traits. This intuition is justified by the fact that the RMP is the denominator in $LR_g = P(g|S)/P(g|D)$. Reducing the RMP by a factor of 10 therefore increases the likelihood ratio by this same factor. Although the RMP is only part of the full likelihood picture (a fact that makes its use inappropriate in cases of mixed DNA stains), its use is comparable to the statistician’s p -value as a gauge of probative value. The statistician may reject a null hypothesis when, under the null hypothesis, the probability of finding an outcome as extreme as (or more extreme than) the one observed is small. The underlying logic is that if the match is unlikely to arise under this hypothesis, then the match is unlikely to be merely coincidental.

Of course, rejecting the hypothesis that the suspect is unrelated to the source of the crime-scene sample but just happens to have the same genotype leaves open various explanations. For example, the crime-scene DNA might not be the suspect’s because of an error in inferring the genotypes or labeling the samples. Or the crime-scene DNA might be the suspect’s, but someone other than the suspect might have deposited it there.

With any type of evidence for which RMPs are available, care also must be taken to avoid naively transposing the conditional probabilities. An RMP of 0.1%, for example, should not be misreported or misconstrued as a 99.9% chance that the trace originated from the defendant. The extent to which naive transposition is in error depends on both the probability of the match given D and the prior probability of S , since these factors also determine the posterior odds. Although transposition may sometimes be harmless error, it is always a conceptual error that can lead to problems in courtroom presentations.

Reporting Likelihood Ratios Quantitatively or Qualitatively

We have seen how likelihoods determine the strength of the evidence in favor of a particular hypothesis. One way to present a likelihood ratio is to say that it tells the number of times it is more probable to see a match when the samples originate from the same source than when they come from difference sources. Analogies can be made to clinical medicine. For example:

The match here is like the symptoms of a disease. The symptoms appear LR times more often when patients have the disease than when they do not. They do not establish for certain that the patient has the disease, but they make the odds LR times greater that he does.

As with the match probability, in a quantitative presentation, care is required to avoid the fallacy of the transposed conditional (also called the prosecutor’s fallacy in legal circles). An LR of 1000, for instance, does not mean that S is 1000 times more likely than D (making the probability of S is $1000/1001 = 0.999$). To a Bayesian, it means that whatever the odds of S may have been, they have gone up by a factor of 1000. If the rest of the case against a defendant is very weak – imagine, for example, that a similar case could have been brought against 500 other people – then the posterior odds on S are roughly $1000 \times 1:500 = 2:1$, corresponding to a posterior probability of only $2/3 = 0.667$.

A number of authors propose expressing the likelihood ratio as a qualitative statement about the strength of the evidence. One table recommends expressions ranging from 'limited evidence to support' ($1 < LR \leq 10$) to 'very strong evidence to support' ($LR > 10000$). Indeed, such phrases may be the best that can be made when adequate sampling and modeling to estimate how many matching items there would be in the relevant population have not been conducted. Although jurors may be hard-pressed to appreciate the difference between gradations such as 'moderately strong evidence' and 'strong evidence,' this approach confines the analyst to opining on the power of the evidence. Supporters of the approach see this as a great strength, but other experts would prefer to address hypotheses like *S* and *D* more explicitly. Trying to do so quantitatively raises legal issues.

Reporting Posterior Probabilities Quantitatively

Testifying about posterior probabilities has produced a contentious literature with a disorderly array of judicial opinions. A major difficulty with incorporating Bayesian computations of source probabilities into forensic work is that the forensic expert is not normally well situated to estimate prior odds that depend on nonscientific evidence in the case. Several procedures have been discussed or used in particular cases: (1) applying a uniform prior distribution across the suspect population; (2) assuming that the prior probability is one-half; and (3) producing a list of posterior probabilities for a range of priors.

First, in some cases, it may be possible to enumerate a small suspect population. In *State v. Klindt*, 389 N.W.2d 670 (Iowa 1986), the prosecution sought to prove that a torso found in the Mississippi River was the remains of a woman named Joyce Klindt. Four women had been reported missing in four nearby states. A statistician computed likelihoods based on immunogenetic markers and other information about these women. He assumed that each woman was equally likely to be the one whose body was found. At the murder trial of Joyce Klindt's husband, the statistician testified that "the probabilities were over 99% that the torso was Joyce Klindt's rather than any of the other three" (Id. at 671). The court did not discuss the statistician's assumption that the prior probability with respect to each woman was 1/4.

Even when the suspect population is indeterminate, one could start with a prior probability assuming that everyone (or every object) in some geographic region is equally likely to be the source and then adjust it in light of the scientific evidence. Suppose the LR for a DNA match to a bloodstain in New York City is 1 000 000. If all residents of New York City (now ~8 000 000) were equally likely to have left the stain, then the prior odds of *S* to *D* would be 1:8 000 000, and the posterior odds would be 1 000 000 times that, or 1:8. The prosecutor then would have to point to other evidence to raise the posterior odds into the beyond-a-reasonable-doubt range. Unlike eqn [2], which requires conditioning on all the nonscientific evidence in the case, this computation tries to ignore all such evidence by regarding the matching test result as the first item of evidence to consider.

This approach resembles the suggestion of the English Court of Appeals in *R. v. Doherty* (1997), 1 Cr. App. R. 369,

374, that a DNA expert should "say how many people with the matching characteristics are likely to be found in the United Kingdom – or perhaps in a more limited subgroup, such as, for instance, the Caucasian sexually active males in the Manchester area." A few commentators with similar ideas have cautioned against 'speculation' and urged that any 'guess' take the form of an "interval . . . set wide enough to have a high probability of including the actual number that might be in the pool" (Saks and Koehler, 2004, p. 217). Mathematically, there is not much difference between quoting a posterior probability of $1/n$ and reporting that there are n or so equally likely suspects or objects that could not be excluded. However, framing the evidence as the number of individuals who could not be excluded by exhaustive testing invites the jury to think about these many alternatives to the prosecution's theory and the fact that the state has not tested many other possible sources. Some research suggests that this creates a weaker impression on the jury than giving a posterior probability that focuses their attention on the defendant.

A second approach to the prior probability of *S* is to assume that its value is one-half. This assumption is made in so-called one-man paternity cases. In these cases, the competing hypothesis usually is taken to be that a 'random man' is the father and to have half the initial probability mass. Testimony as to the resulting posterior probability, with or without disclosure of the prior odds of 1:1, usually was admitted with little appreciation of the nature of the computation, but more recent criminal and civil court cases on the admissibility of Bayesian presentations with these artificial priors reach conflicting results.

In the third and final procedure that could be applied to Bayes' rule explicitly in court, the expert clearly communicates that the prior odds are for the judge or jury to ascertain. Jurors then can be invited to select the prior probability on the basis of the other evidence in the case, and advised to use the trace evidence according to Bayes' rule to deduce a posterior probability. A better solution might be to present a table of prior and posterior probabilities to demonstrate the power of the matching trace evidence. This variable-prior-probability method does not force jurors to articulate the prior odds, and this avoids certain logistical, psychological, and jurisprudential difficulties that confront the juror-choice-of-prior-probability method.

Categorical Source Attribution

For most types of trace evidence, probability models for feature sets are not well established and frequency data are limited. What is a forensic scientist to do? In some fields, the convention is to eschew interpretation by merely reporting consistency of features or an inability to exclude. Of course, this leaves the fact finder uninformed about the importance of the match, but if nothing more is known and research establishes that the analysis of the features has some discriminating power, then a candid recitation of these facts may be better than nothing.

At the other extreme, pattern-matching experts such as latent fingerprint examiners, have long claimed the ability to attribute a mark to the single source from which it came because there is (or so they postulate) no chance of any other possible source producing exemplars as similar to the

crime-scene mark as the one they have for comparison. But the theory of unique identification, as opposed to a highly probable identification, is all but impossible to validate. As a result, there is movement toward the less dogmatic view that a fingerprint match based on a sufficiently clear and extensive latent print makes it very likely that an examiner's positive identification is correct for suspect populations of realistic sizes. Although it might be preferable merely to describe the results of the comparison as providing very strong evidence for S, offering a specific source attribution is scientifically defensible if its probabilistic nature is made clear and controlled experimentation demonstrates the ability of analysts to distinguish reliably and accurately between appropriate samples from the same source and samples from different sources.

This article is a revision of the previous edition article by D. Canter, volume 3, pp. 1091–1097, © 2000, Elsevier Ltd.

Introduction

The domain of investigative psychology covers all aspects of psychology that are relevant to the conduct of criminal or civil investigations. Its focus is on the ways in which criminal activities may be examined and understood in order for the detection of crime to be effective and legal proceedings to be appropriate. As such, investigative psychology is concerned with psychological input to the full range of issues that relate to the management, investigation, and prosecution of crime. Detectives and others involved in these investigations become decision makers at each stage of the process, and need to identify the possibilities for action on the basis of the information they can obtain.

This investigative decision making involves the identification and selection of options, such as possible suspects or possible lines of inquiry, that will lead to the eventual narrowing down of the search process. In order to generate possibilities and select from them, detectives and other investigators must draw on some understanding of the actions of the offender(s) involved in the offense they are investigating. They must have some idea of typical ways in which offenders behave that will enable them to make sense of the information obtained. Throughout this process, they must amass the appropriate evidence to identify the perpetrator and prove their case in court.

It follows that three processes are always present in any investigation that can be improved by the psychological study. First, the collection and evaluation of information derived from accounts of the crime. Once suspects are elicited, there is further potential information about them, either directly from interviews with them or indirectly through reports from others. In addition, there may be information from various experts that has to be understood and may lead to actions. The major task of a police investigation is, therefore, typically to collect, assess, and utilize a great variety of sources of information that provide accounts of crime. This is a task that can benefit considerably from the scientific study of human memory processes and other psychological studies of the reliability and validity of reports and their assessment.

The second set of tasks is the making of decisions and the related actions that will move toward the arrest and conviction of the perpetrator. From many studies of human decision making in other contexts, it is also apparent that there are likely to be many heuristic biases and other inefficiencies in the decision-making process. Awareness of these can lead to effective ways of overcoming them.

In order for decisions to be derived from the information available, inferences have to be made about the import of that information. The third set of tasks therefore derives from developing a basis for those inferences at the heart of police investigations. These inferences derive from an understanding

of criminal behavior. For appropriate conclusions to be drawn from the accounts available of the crime, it is necessary to have models of how various offenders act. These models allow the accounts of crime to be processed in order to generate possibilities for action. This process of model building and testing is, in effect, a scientific, psychological development of what is often referred to as 'offender profiling.'

In summary, investigative psychology can be summarized as the systematic, scientific study of

- investigative information, its retrieval, evaluation, and utilization;
- police actions and decisions, their improvement, and support; and
- the inferences that can be made about criminal activity, its development, differentiation, and prediction, with the objective of improving criminal and civil investigations.

Information Retrieval

There are many psychological questions raised in relation to the retrieval of information during a police investigation, and various studies have led to the development of procedures to improve the information collected during an investigation. This includes the most valid and reliable way whereby it is possible to obtain information from either the crime scene, the victim, the witness, or the offender, that can ultimately form the base of all analysis.

Interviews

One of the most important aspects of the information obtained during an investigation is that it should have as much relevant detail as possible. Psychologists have therefore helped to develop processes, especially for police interviews, that maximize the information obtained. In doing this, the perspective is taken that there are two issues that need to be as effective as possible. One is based on the assumption that the respondent in an interview is essentially trying to remember what occurred. Therefore, anything that can help the memory process should be of value. The second issue is the relationship between the interviewer and the interviewee. If this relationship can be as supportive and helpful as possible, then more effective information is likely to be obtained.

Out of these considerations, guidelines for interviews have been developed. The best known of these is referred to as the 'cognitive interview.' This is based on the assumption that memory is an active reconstructive process rather than a relatively passive act of recall. It draws on the well-established finding that recognition of information is much easier than its recall. Therefore, any procedure that can help the interviewee to

recreate the events in his or her own mind will be of value. This includes encouraging respondents to describe the events as they remember them rather than in strict response to particular questions in a given sequence. Reinstating the circumstances of the offense whenever possible, by returning to the scene or exploring details like sounds and smells, also accords with an understanding of the psychological processes by which memories are reconstructed. Attempts to consider the events from a variety of different perspectives are also considered valuable.

A number of studies have shown that the cognitive interview generates significantly more detailed information than conventional police interviews. Some studies show that the information obtained is more accurate, and also that more relevant information is obtained, but it is remarkably difficult to measure relevance or accuracy precisely; so the full value of the cognitive interview is likely to vary considerably between situations.

Witness Recall

Attempts have also been made to use similar psychological processes to improve the recollection of faces and other details.

Psychological research has also contributed considerably to the improvement in the validity of the traditional 'identity parade.' Various procedures have been introduced by many police forces around the world to ensure that the recognition task set for the witness is appropriate and not open to bias. In particular, these take account of the need to protect the suspect against the possibility of the witness's memory being modified by experiences subsequent to the crime, such as meeting the suspect in other circumstances.

Vulnerable Interviewees

A number of witnesses may be regarded as vulnerable because of their age, emotional state, or intellectual ability. Such witnesses may be particularly open to suggestion or may be made especially anxious or confused by the interview process. Special interview procedures have therefore been developed for interviewing such people. The procedures pay particular attention to the relationship established between the interviewee and the interviewer and the need to phrase questions and facilitate answers in ways that make sense to the respondent.

False Confessions and Allegations

Psychologists have drawn attention to the possibility that some individuals may confess to crimes they have not committed. These 'false confessions' may be a consequence of characteristics similar to those that make witnesses vulnerable, such as emotional state and intellectual ability, making the suspect more willing to accept suggestions from the interviewer. These may also be a product of cultural processes rather than aspects of personality, in which, for example, groups from certain ethnic minorities may deem it essential to agree with whatever a person in authority, such as a police officer, says to them. Investigative psychologists have also considered the ways in which false confessions may be produced in response to various forms of psychological or physical coercion.

In many circumstances, investigators wish to assess the validity of information from witnesses because they consider

that allegations may be false. If there are no objective criteria for doing this, they may use one of a number of validity assessment techniques. Most of these techniques are based on the assumption that honest accounts have identifiable characteristics that are different from fabricated accounts. The most frequently used approach to statement validation is the statement validity assessment, which draws upon detailed analysis of the content of a statement, referred to as criteria-based content analysis. This procedure has been widely used to evaluate allegations of abuse made by children.

Authorship

A subset of validity questions relate to whether the words attributed to a particular author are actually the words of that person or not. This may occur, for example, when a suspect denies that he or she made the statement attributed, or in other cases of forgery or fraud. To deal with these questioned utterances, there have been a variety of attempts to use techniques based on the quantitative examination of language. These approaches are sometimes put under the general heading of 'stylistics,' or forensic linguistics, or more generally forensic psycholinguistics.

These procedures are not to be confused with 'graphology,' which claims to be able to provide accounts of the personality of an author from the style of his or her handwriting. There is no consistent scientific evidence for these claims.

Detecting Deception

When the suspect is the source of the information, additional factors are also important beyond those of memory retrieval. These often relate to the need to determine whether a person is attempting to deceive the interviewer. Thus, although there are many objective, conventional police strategies for detecting deception, most obviously determining if the known facts contradict the suspect's claims, there are a number of situations in which some knowledge of behavioral and psycholinguistic cues to deception would be very helpful. A number of researchers have claimed that such cues are available, but others are more skeptical as to the possibility of any generally available indexes of deception from the actions or words of the suspect during a police interview.

Another technique that has also been put forward to evaluate deception is the polygraph or 'lie detector,' which records changes in the autonomic arousal system, that is, emotional response. Such responses occur whenever a person perceives an emotionally significant stimulus. The most well-established indicator is when the respondent is asked to consider information that only the perpetrator would be aware of, known as the 'guilty knowledge' test. Scientific support for this technique is still being developed, and many jurisdictions do not allow 'lie detector' results to be presented as evidence in court.

Investigative Decision Making

The main challenge for investigators is to make important decisions in often ambiguous and sometimes dangerous circumstances. The events surrounding the decisions are likely to carry

a great emotional charge and there may be other political and organizational stresses that also make objective judgments very difficult. A lot of information, much of which may be of unknown reliability, needs to be amassed and digested. The general literature in decision-making psychology shows that these are conditions that may lead to biases in thought processes, and consequently decision making. Recognition of the potential for these problems can lead to the development of procedures to reduce their likelihood. The challenges of police and other investigations may also be reduced by the development of decision support tools that reduce the complexity of the information that needs to be understood and assists in the derivation of appropriate inferences from the material that is available to the police. The decision support tools that are emerging for use by police investigators all draw on particular perspectives on the nature of the problem.

Visualization

Some support tools are based on the fact that human beings can often see patterns between associations, and within activities, if they can be presented in some form of visual summary. Bar charts of frequencies are one common example of this, but commercially available software will chart networks of contacts and other sequences of associations or actions. While these tools can be productive in summarizing a great deal of information and, in association with databases, can improve the search for and access to crucial information, they are very dependent on the skills of the particular user, often referred to in police forces as a crime analyst. In the wrong hands, these systems can imply a behavioral pattern through the strong visual impact that a diagram produced, when in fact the diagram is a biased emphasis of some peripheral aspect of the criminal behavior being investigated.

Description

A further level of support to decisions can be made by identifying the salient characteristics of the offenses and offenders and by producing summary accounts of them. One widespread application of this use is in the production of maps that indicate the locations where there are high frequencies of crimes, sometimes called criminal hot spots. In these cases, the salient characteristics are simply where the crimes have occurred, and the description consists of some summary or averaging of the crimes over an area in order to indicate where its geographical focus might be. All description requires some selection, distillation, or averaging of information, and when that is done validly, the description is helpful.

Analysis

A further level of assistance to police decision makers can be given by carrying out some form of analysis on the crime material, typically looking for patterns of co-occurrences or discriminating nonoccurrence. An example of the former would be the recognition that certain acts of vandalism occur shortly after the end of the school day near to schools. Knowledge from descriptive analyses of the age and backgrounds of offenders prosecuted for vandalism and the geographical

hot-spot information could be combined to target possible culprits and introduce other forms of crime reduction. More advanced analysis of the co-occurrence of criminal behaviors could also be used for classifying offenders and generating different investigative strategies for the different forms of offenders.

Inference

When clear relationships can be established between different aspects of crimes that are of investigative interest, inferences can be made from one to the other. For example, an understanding of the relationships between where an offender offends and where he or she lives can be used to infer residential location from knowledge of offense location. The use of inference for decision support activities is at the core of the area popularly known as 'offender profiling,' which will be dealt with in more detail below.

Appropriate Inferences

The main psychological premise behind profiling is that there will be a consistency between the way offenders act at the crime scene and their characteristics. This is based on the broader literature based on longitudinal studies and cross-situational consistency in general as well as from findings on the development of criminal behavior.

In many ways, behavioral profiling follows the same procedure as forensic science, which is another tool in police investigations, with the same aim of analyzing the evidence at the crime scene. But rather than focusing on the biological and chemical components of the crime scene, profiling focuses on the behavioral element. In cases where forensic evidence has been compromised or where the offender has cleaned the crime scene so as not to leave a trace, behavioral evidence is much more difficult to remove from the crime scene and traces of behavior will usually always be present no matter what the offender does. For example, if you have an offender who removes forensic evidence from the crime scene, that itself is a piece of behavioral evidence, because the mere fact that the offender is either not leaving forensic evidence (i.e., coming prepared to the crime scene) or removing it from the crime scene indicates something about the type of offender he/she is.

This has often been referred to as the A → C equation, where that the aim is to link the actions that occur during the offense, including when and where it happens and to whom, to the characteristics of the offender, including the offender's criminal history, background, and relationships to others.

Three general interlinked areas have been the focus of recent research in offender profiling: individual differentiation, behavioral consistency, and inferences about offender characteristics.

Individual Differentiation

The first step in profiling is to devise a method for determining individual differentiation or for comparing individuals in terms of conceptual categories. This step in profiling is normally referred to as determining the 'actions' (A) of the

offender during the crime in question. The idea behind this process is that offenders engage in various ways of acting at the crime scene. These conceptual categories generally include subgroups of behaviors with the same underlying psychological theme or significance for the offender.

Individual differentiation aims to establish differences between the behavioral actions of offenders in order to identify the type of crime that has been committed. The focus here is on analyzing the observable, rather than motivational, aspects of the crime to increase the reliability and practical utility of these models in actual investigations. Although it is important to gain insight into the cognitions of offenders and add these to emerging models, research has shown that motivations are inherently more subjective and difficult to measure. As such, behaviors provide a more reliable unit of analysis, at least at the first stages of building models of criminal differentiation that are valid, reliable, and ultimately useful and applicable to actual investigations. Another important issue is that the variables on which they can draw are limited to those of use to police investigations. This implies that the A (action) variables are restricted to those known prior to any suspect being identified. The C (characteristics) variables are limited to those on which the police can act. So, the offender's personality characteristics, detailed measures of intelligence, attitudes, and fantasies are all of less utility than information about where the person might be living, and his or her criminal history or domestic circumstances.

Behavioral studies of differentiation usually focus on differences among crimes scenes in various observable factors, including victim characteristics, interaction with the victim, nature of the violence, and other activities engaged in by the offender at the crime scene. Much of this work has aimed to understand how an offender engages in patterns of actions that all demonstrate a similar underlying psychological dimension. Any crime can be profiled using the appropriate frameworks, and work to date has included theft, burglary, robbery, arson, fraud, rape, pedophilia, crimes committed by youths, homicide, serial homicide, and others. The relevant psychological dimensions depend on the crimes analyzed. Some examples used in homicide work include behaviors indicative of expressive and instrumental types of aggression – such as treating a victim as an object or as a person, acting in a controlled or an impulsive manner – all of which are already well-established thematic classifications of human behavior in the general psychological literature.

Behavioral Consistency

Behavioral consistency is critical to differentiating individuals and is the second key issue in empirical studies of offender profiling. Behavioral consistency comprises two separate yet interrelated fields of study. The first aims to look at the consistency across an individual's series of crimes; this is typically referred to as 'linking.'

The key research questions in the area of linking are whether crime scenes can be linked to each other and thereby an individual series can be identified while also identifying how it differs from other series. Specifically, an important question is which behaviors are the most reliable to focus on when making this determination. Running through all these

questions is the key question of what is meant by consistency and how this may be displayed.

Behavioral consistency is a key issue in profiling, specifically for understanding both the development of an offender's criminal career and an individual's consistency across a series of crimes – that is, whether the same subsets of actions are displayed at each crime scene over a series (linking serial crime). Much of this work has focused on whether consistency in criminal behavior can be established over time, as well as how individuals change and develop through learning and experience and whether offenders specialize or are generalists.

The search for consistencies has been approached in various ways in the theoretical literature, notably by establishing whether the offender acts according to the same psychological subtype or theme from one crime to the next, whether the offender engages in the same specific behaviors from one crime to the next (*modus operandi*), or whether the offender engages in highly specialized behaviors unique to them and that are related more to their personal agenda, or fantasies (*signature*). The first few published studies on empirically validating these theoretical concepts indicate that although some consistency is evident, our understanding of the intricacies of the actual patterns over time requires closer empirical study, specifically in terms of how offenders experiment, learn, develop, mature, and change in a consistent manner across time, as well as how situational factors influence an offender's behavioral consistency.

Experimentation

Apparent inconsistency may be observed throughout a series, that may be explained by the offender experimenting, trying out new behaviors from situation to situation. Although there appears to be inconsistency because the actions engaged in are visually different, the mere fact that experimentation occurs may be evidence of a certain type of offender, and could thus be a marker for consistency.

Learning

Most offenders will learn from their experiences. They will therefore be expected to alter their actions in the light of the consequences of previous actions. An inferential implication of this is that it may be possible to link crimes to a common offender by understanding patterns and reasons of how behavior has changed from one offense to the next.

Development

The unfolding psychological mechanisms that come with age provide a basis for change in cognitive and emotional processes. One reflection of this is an increase in expertise in doing a particular task. Evidence of such expertise in a crime can thus be used to help make inferences about the stages in a criminal's development that he or she has reached, and indeed to indicate the way the crimes might change in the future.

Maturation

This is the, essentially biological, process of change in a person's physiology with age. Knowledge of what is typical of

people at certain ages, such as sexual activity, can thus be used to form a view as to the maturity of the person committing the crimes and to the basis for longer term variations in an individual's criminal activity.

Situation

One important reason for differences between a criminal's actions on two different occasions may be their reaction to the different circumstances faced. By understanding these circumstances and how the offender has responded to them, some inferences about their interpersonal style or situational responsiveness may be made, and can be another marker for consistency, and can have investigative implications.

Inferences About Offender Characteristics

Inferences about offender characteristics is at the core of profiling and also uses consistency analysis as its main focus. At this stage, however, the main aim is to establish the link between the subtype of crime scene actions engaged in and associated offender characteristics in order to make predictions about an offender based on their criminal actions at the crime scene. This can then ultimately be used as a primary tool for the police to narrow their suspect pool down to statistically the most likely offender. This is the C part of the actions-to-characteristics, or $A \rightarrow C$, equation. Offender characteristics focused on typically include demographics, such as gender, age, and education, previous interpersonal and criminal history, home location and travel patterns (also known as geographical profiling), and the offender's relationship with the victim.

Operational Applications

All of the attempts to solve the $A \rightarrow C$ equations are related to attempts to help answer the following operational questions:

1. Which suspects are most likely to have committed the crime in question?
2. Which crimes in a series are likely to have been committed by the same offenders?
3. What are the salient characteristics of the offender that will help investigators to identify and locate them?

4. Where, geographically, should searches for offenders be carried out?
5. What searches of police records or other sources of information should be carried out to help identify the offender?
6. What sense can be made of the offense that will help to organize the legal case?

Glossary

Brain fingerprinting A method for detecting concealed information stored in the brain by measuring and analyzing electroencephalographic brain responses.

Concealed information test A lie detection test designed to detect lies regarding concealed information or knowledge that may be indicative of guilt.

Control question test A lie detection test involving measurement of psychophysiological responses to relevant, irrelevant, and control questions.

Electroencephalography (EEG) The measurement of electrical brain activity noninvasively from the scalp to detect patterns of brain activity.

Fight-or-flight response A psychophysiological response to real or perceived danger that prepares the body for strenuous physical activity.

Functional magnetic resonance imaging (fMRI)

A technique for measuring blood flow in the brain noninvasively, thereby providing information on brain activity.

Galvanic skin resistance (GSR) Changes in the resistance of the skin to an electrical current that can be measured in order to provide information on sweat gland activity, and indirectly on emotional responses.

Galvanometer An instrument for measuring a small electric current; used in psychophysiology in the measurement of galvanic skin resistance.

Guilty knowledge test A lie detection test designed to detect lies regarding concealed information or knowledge that may be indicative of guilt.

Laser Doppler vibrometry A method for using the Doppler shift in laser light to measure changes in fluid flow or vibration; used in psychophysiology for measuring blood flow and other bodily processes noninvasively.

Millisecond One one-thousandth of a second.

Plethysmograph An instrument for measuring peripheral blood flow noninvasively.

Polygraph An instrument for measuring several psychophysiological variables continuously; particularly, such an instrument used for lie detection.

Psychophysiology The study of the relationship between psychological, emotional, or mental phenomena and physiological responses or states.

Skin conductance response (SCR) Changes in the conductivity of the skin to an electrical current that can be measured in order to provide information on sweat gland activity, and indirectly on emotional responses.

Lie Detection and Truth Discovery

The goal of lie detection is the discovery of the truth. Lie detection methods can be applied when one person knows the truth about an event and another person seeks to discover that truth. This is particularly important in situations where successful truth discovery has major consequences, such as an interrogation of a suspect by an investigator.

In virtually every case, the perpetrator of a crime knows who he is. An intelligent and savvy criminal may eliminate all external evidence of his crime. Even the cleverest criminal, however, cannot expunge his own knowledge of his participation, at least not without destroying his life or his ability to function mentally. The record of the crime stored in the brain of the perpetrator is readily accessible to him, but hidden from investigators. The goal of lie detection, and of truth discovery in general, is to discover this hidden truth accurately and reliably.

Throughout history, people have sought reliable methods to determine the truth regarding events that have taken place. The various methods of lie detection, or polygraphy as it is commonly called, have grown out of the fundamental desire or need to determine the truth, in situations wherein someone involved knows the truth but may have reason not to report it accurately when questioned. The most common and universal such situation is a criminal investigation.

In short, lie detection – if successful – is a means to accomplish the ultimate goal of truth discovery, and the truth that is being discovered is the record of the crime or other event stored in the brain of the subject.

In the absence of a videotape of the crime, the most comprehensive repository of the truth about the investigated situation is, generally, the record stored in the brain of the perpetrator, and any surviving victims or witnesses.

The most obvious way to discover the truth that is known to one individual and not to others is to ask the person who knows. The difficulty, of course, is that the individual who knows may not reveal his hidden knowledge voluntarily. He may seek to deceive in order to conceal his hidden knowledge. Lie detection comprises various methods to discover the hidden truth by indirectly attempting to detect this deception.

All techniques of lie detection, and all techniques of interrogation, rely on the premise that the subject, if guilty, knows of his role in the crime. An innocent subject does not have knowledge of his role in the crime, because he played no such role. Asking questions about this information and using lie detection methods to attempt to determine whether or not the answers are truthful is a means to the ultimate end of determining whether or not the record of his committing the crime is stored in the brain of the suspect. The goal of lie detection is the discovery of the truth, a truth that is known

by the subject and not by the investigators. All techniques of lie detection are indirect methods of truth discovery.

Brain fingerprinting is a direct method of discovering a truth that is known to the subject and not to investigators. Brain fingerprinting directly detects the record of the crime stored in the brain of the suspect, or the absence of such a record for a suspect who was uninvolved and lacks detailed knowledge of the crime. It detects concealed information stored in the brain by measuring an electroencephalographic brain response known as a P300-MERMER to crime-relevant information presented on a computer screen. In laboratory and field research and applications at the Central Intelligence Agency, the Federal Bureau of Investigation, the US Navy, and elsewhere brain fingerprinting has been over 99% accurate. It has never produced a false negative or false positive error. It has been published in the peer-reviewed scientific literature, replicated in independent laboratories, and applied in the field. Brain fingerprinting helped to catch a serial killer and was ruled admissible in court in the case of a man falsely convicted of murder who was ultimately exonerated and released. The effectiveness of brain fingerprinting depends on following the brain fingerprinting scientific standards.

Brief History of Lie Detection

Observation and Measurement of Overt Behavior

For as long as people have been interested in discovering the truth, people have developed and practiced various methods of attempting to detect deception through overt behavior. Scientific studies of lying and its detection in situations where there is real motivation, however, have shown that even skilled professionals perform little better than chance at detecting lies by observation of behavior alone.

Over the centuries, seekers of truth have developed many techniques of attempting to detect deception through behavioral means. None of these techniques have proven accurate or reliable due to the fact that overt behavior is under voluntary control and hence can be manipulated.

Over the last century numerous experimenters have attempted to use response time as an indicator of deception. Such efforts have never been successful in developing a viable method for lie detection, however, because reaction time like other overt behavior is under voluntary control and is readily manipulated.

Early Psychophysiological Lie Detection

Fortunately, overt behavior is not the only indication of whether or not someone is lying or has something to hide. Over 2000 years ago experts recognized that psychophysiological responses reveal what a person's words and overt actions may conceal.

The first practice of psychophysiological lie detection recorded in detail was by the Greek physician and physiologist Erasistratus in the third century BC. He observed that when his subject was trying to conceal the truth, "his face flushed up . . . a sudden sweat broke out on his skin, the beatings of his heart were irregular and violent . . ."

The 'sudden sweat' described by Erasistratus constitutes a primary symptom recorded by modern polygraphs. The

'irregular and violent beatings of the heart' – another major response recorded in modern lie detection – could only have been observable if Erasistratus had actually taken the pulse at the appropriate times.

Here Erasistratus exhibits a sophisticated theoretical understanding of psychophysiology, the same theoretical understanding that forms the basis of all modern conventional lie detection prior to the invention of the brainwave-based system discussed herein.

It is clear that the theoretical foundations of conventional polygraphy, and indeed a recognition of many of the critical psychophysiological responses to be measured, are founded on a 2000-year-old tradition. Modern conventional lie detection techniques have built upon this foundation with sophisticated instrumentation and have developed a rich empirical database.

Over the next 2000 years many others made similar psychophysiological observations as a means of lie detection, and some developed techniques of actively manipulating the situation using controlled stimuli to elicit the telltale psychophysiological responses at predictable times.

Modern Psychophysiological Lie Detection and Scientific Instruments

Polygraphy, the use of scientific instrumentation in psychophysiological detection of concealed information, began in the late nineteenth century with rudimentary measurements of blood pressure. In 1915, Harvard professor William Marston, often credited with the invention of the lie detector, began a series of experiments using blood pressure in the detection of deception. He used an ordinary blood pressure cuff to record blood pressure periodically during questioning. Marston also recorded breathing patterns and experimented with skin resistance.

Over the next several decades, innovators developed various refinements of the instrumentation and measurements used in polygraphy. By the middle of the twentieth century, the essential features of the modern polygraph had been established.

John Reid is often credited with first introducing the control question technique that is most commonly used in conventional lie detection. He refined this technique to essentially the same form in which it is practiced today. Reid and his colleague, Fred Inbau, did much to systematize the methods for questioning and data acquisition in polygraphy. Over the years, they accumulated voluminous data on the applicability and effectiveness of various techniques of conventional lie detection.

Theories of Lie Detection

The fundamental theoretical premise of conventional psychophysiological lie detection is twofold: (1) the act of deception is accompanied by a different emotional response than the act of truth telling; and (2) this different emotional response results in a different, measurable, physiological response. This fundamental premise formed the basis of the practice of lie detection for thousands of years.

Modern scientists have explained this psychophysiological phenomenon in terms of the body's preparation to deal with a physically dangerous situation, driven by the emotions that accompany an encounter with a real or perceived danger.

The perception of a potential physical danger elicits emotional arousal, including fear as a major factor. In the presence of such emotional arousal, the body prepares for the intense physical activity that may be necessary to respond to the threat by fighting or fleeing. In this 'flight-or-fight' response, the blood pressure and heart rate rise in preparation for vigorous physical activity. Perspiration is elicited to cool the body in preparation for the anticipated physical activity, and to provide better traction on the palms and soles of the feet. Changes in breathing take place as well. Breathing may become more irregular. Breathing may pause or be restricted momentarily as part of a 'freezing' response meant to keep the body still and thus less noticeable in the presence of danger.

Psychophysiological lie detection techniques measure several psychophysiological variables that are a part of the fight-or-flight response characterized by the general arousal involved in preparation for physical activity.

The fundamental theory of conventional psychophysiological lie detection has remained essentially the same for over 2000 years. It has been shown, however, that a unified theory of arousal is inadequate to explain some observed phenomena. Modern psychophysiologicalists have distinguished between different responses such as the orienting reflex and the defensive reflex.

Along with a more fine-grained understanding of the responses involved, recent years have seen some elaborations and variations to the basic theory. Modern experts have proposed the following theories of psychophysiological lie detection:

1. The fear theory holds that the relevant questions in a conventional polygraph test elicit fear of the consequences of being caught in a lie, which in turn produces the physiological responses measured.
2. The arousal theory holds that detection occurs because of the different arousal value of the various stimuli.
3. The conditioned response theory holds that the critical questions play the role of conditioned stimuli and evoke some emotional response with which they have been associated in the past. One difficulty with the conditioned response theory is that it is insufficient to explain psychophysiological responses to lying about rather trivial matters with which the subject has had no past experience.
4. The conflict theory presumes that a specially large physiological disturbance occurs when two incompatible reaction tendencies are aroused at the same time. The assumption is that a subject has the habit of telling the truth, but in a situation necessitating deception to maintain his/her innocence the subject would simultaneously experience an opposite tendency.

These elaborations of the basic theoretical foundation for lie detection are not mutually exclusive. Moreover, it is likely that several different aspects of the psychophysiological phenomenon underlying conventional lie detection take place simultaneously.

These theoretical distinctions, however, have by and large not been important for the actual practice of conventional polygraphy. Established on the original theoretical foundation recognizing the link between emotions and physiological responses, polygraphy has proceeded primarily empirically. A strong psychophysiological response of any one of a number of flavors has been deemed sufficient to reveal that a relevant stimulus is emotionally arousing for an individual. In practice, polygraphers have come to recognize a wide variety of different, sometimes opposite, responses as indicators of the state or states of heightened emotion that are hypothesized to accompany deception.

Psychophysiological Measurements in Modern Lie Detection

The Conventional Polygraph

The conventional polygraph or lie detector measures three psychophysiological metrics.

Blood pressure is monitored continuously by a blood pressure cuff on the arm. This also provides a measure of heart rate because the individual pulses can be observed as abrupt periodic changes in blood pressure.

Changes in breathing patterns are measured by straps across the chest that record the expansion and contraction of the chest.

Skin conductance or galvanic skin resistance is measured by a galvanometer attached to the fingers. The conductance of a slight electric current across the skin of the hand is a very sensitive measure of sweating and can pick up slight changes that are not observable to the eye.

Alternative Psychophysiological Metrics

Fear, conflict, and other emotions that may accompany lying have numerous other physiological correlates in addition to the ones commonly measured by the conventional lie detector. Scientists have experimented with numerous other psychophysiological metrics either in addition to or as an alternative to the metrics of the conventional polygraph. The theory underlying the use of these alternative metrics is the same as the theory of the conventional lie detector: Deception produces emotional changes; emotional changes produce measurable psychophysiological responses.

The pupil of the eye is known to dilate with emotional arousal. Experimenters have attempted to apply this phenomenon in lie detection through various means of recording and quantifying the changes in the pupillary diameter.

For the measurement of cardiovascular activity, some polygraph systems include a plethysmograph that measures blood flow in a finger. These measurements have proven to be relatively reliable.

Recently, laser Doppler vibrometry has shown promise as a sensitive metric of changes in arterial blood flow that can be applied noninvasively.

Changes in cardiovascular activity are also reflected in patterns of changes in skin temperature, particularly on the face. Experimenters have measured these changes through thermal

imaging in an attempt to detect patterns indicative of the emotions accompanying lying.

Experimenters have applied techniques to measure cardiovascular activity in the brain in an attempt to measure the changes in brain activity accompanying the emotions that may accompany lying. In one technique, near-infrared light is shined through the head. The amount of light reflected back reflects blood flow in different regions.

Functional magnetic resonance imaging (fMRI) is another technique to measure blood flow in the brain. It is based on the same fundamental theory of deception as the conventional polygraph. The conflict theory discussed above was proposed in the 1960s to explain the physiological changes that characterize fear and/or arousal during deception. More recently, the same theory has been advanced as a justification for measurements of cerebral blood flow in attempts to detect deception. It has been hypothesized that the conflict between the natural tendency to tell the truth and the action of telling a lie results in changes in cerebral blood flow to different parts of the brain, as well as the more commonly measured changes recorded by the conventional polygraph.

fMRI produces an image of the brain that reveals patterns of blood flow to different areas. Two different commercial companies have proposed two different patterns as indicative of the conflict that is hypothesized to accompany deception. It remains to be seen whether fMRI will prove to be more effective than the conventional polygraph for measuring the physiological correlates of the emotional changes that may accompany deception.

Lie detection through voice stress analysis is based on the hypothesis that lying produces consistent, measurable, emotion-related changes in the voice. A number of voice stress analysis lie detection systems have been developed commercially. Controlled studies, however, have consistently failed to produce better than chance accuracy in detecting lies with this technology.

Research on these and other alternative techniques continues. As of the present time, none of the alternative methods have proven to be more reliable or accurate for detecting the physiological correlates of the emotions that may accompany lying than the conventional polygraph measuring cardiovascular activity with a blood pressure cuff, skin conductance, and breathing.

Conventional Lie Detection Techniques

Types of Questions

The various conventional lie detection tests use different subsets of four basic types of questions.

1. Relevant questions are direct questions about the issue at hand, for example, 'Did you shoot Mr. Jones?'
2. Irrelevant questions are irrelevant and are designed not to be emotion eliciting, for example, 'Are you now in New York?'
3. Control questions, also called comparison questions, are not relevant to the issue at hand, and are designed to elicit a strong emotional response. They are often designed to be vague, so that the subject may lie about them or may be

unsure of whether he is lying or not. An example is, 'Before this year, did you ever lie to a person in a position of authority?'

4. Concealed information questions inquire about a subject's knowledge of a specific feature of the investigated situation, for example, 'Regarding the murder weapon, do you know that it was a knife?' They can be considered a type of relevant questions.

Types of Conventional Lie Detection Tests

The relevant/irrelevant test

Early polygraph tests comprised two types of questions: relevant questions and irrelevant questions. The theory was that the relevant questions would elicit a much larger response than the irrelevant questions for a deceptive person, and the responses to relevant and irrelevant questions would be more similar for a truthful person. The primary shortcoming of the relevant/irrelevant (R/I) test is that it is obvious to the subject which questions are relevant, and the relevant questions are often about highly emotionally charged matters, whether the subject is truthful or deceptive. Due to this shortcoming, the R/I test is rarely used today in investigations of specific incidents. It is still sometimes used in screening tests such as preemployment screening, where the relevant questions are of a general nature.

The control question test or comparison question test

The control question test (CQT) was introduced in the mid-twentieth century to address the shortcomings of the R/I test. It includes relevant and irrelevant questions, plus a third type of questions, the control or comparison questions.

As described above, control questions are designed to elicit a strong emotional and corresponding physiological response in all subjects, whether they are deceptive or nondeceptive. The theory is that for a deceptive subject, the relevant questions will elicit an even larger response than the control questions, whereas for a truthful subject the relevant questions will elicit a smaller response than the control questions. Irrelevant questions are not considered in evaluating results.

The guilty knowledge test or concealed information test

The guilty knowledge test (GKT) or concealed information test attempts to detect deception regarding a subject's knowledge of specific details about an investigated situation. Like the R/I test, the test includes relevant and irrelevant questions. They are of a different format than those of the R/I test, however. The relevant questions refer to a specific, correct feature of the investigated situation, for example, 'Did the crime take place in the living room?' Irrelevant questions specify similar but incorrect features, for example, 'Did the crime take place in the kitchen?' There are several irrelevant questions for each relevant question.

The theory is that if the response to the relevant question is larger than the response to the irrelevant questions, the relevant questions have elicited an emotional and corresponding telltale physiological response, and the subject is lying about his knowledge of the information in question.

The Legal Status of Lie Detection

The US Supreme Court ruled the polygraph inadmissible as evidence in the 1923 Frye decision that became the standard for admissibility of scientific evidence. The Frye standard holds that admissible scientific evidence must meet the standard of general acceptance in the relevant scientific community. The Daubert standard, established by the US Supreme Court in 1993, has largely supplanted the Frye standard in the United States. It is more favorable to novel scientific techniques. In general, conventional polygraph techniques have not been held admissible as scientific evidence in court in the United States under either standard.

Recently fMRI-based lie detection has also failed to gain admissibility in court in the United States.

The situation is similar in other countries, with the possible exception of Japan. Investigators in Japan use the GKT extensively, rather than the CQT that is generally used in the United States. In Japan this use of the polygraph is more widely accepted and has been ruled admissible in court cases.

Unlike the other techniques discussed herein, brain fingerprinting has been ruled admissible in court in the United States.

Criticisms of Conventional Lie Detection

Criticisms of lie detection generally involve questioning the fundamental theory on which all conventional lie detection methods rely. The same fundamental theory forms the basis for the conventional polygraph and its several variations, voice stress analysis, fMRI, and all of the other techniques that seek to measure physiological correlates of deception: Deception produces particular emotions, conflicts, etc.; these emotions in turn produce physiological changes; and these changes can be reliably measured.

The connection between emotions and physiological changes is well established. Criticisms generally focus on the connection between deception and emotions (or conflict, etc.).

Criticisms of the CQT

The CQT relies on the comparison between physiological responses to control questions and relevant questions. (Responses to irrelevant questions are not analyzed.) A larger response to the relevant questions than to the control questions is considered evidence of deception. The opposite is considered evidence of nondeception.

Critics maintain that a nondeceptive subject may nevertheless respond more strongly on the emotional level, and consequently on the physiological level, to the relevant questions for any one of a number of reasons. When the relevant questions are about extremely emotional matters such as a murder or rape, it is difficult to imagine control questions that will produce a larger response even if the subject is innocent and truthful. Lack of a sufficiently large response to the control questions, or a very large response to the relevant questions due to their emotional nature and not to deception, can result in a false positive result, a nondeceptive subject being found deceptive.

On the other hand, a subject who for one reason or another lacks guilt, remorse, or fear in association with his responses to the relevant questions, or who is physiologically unresponsive, may show only relatively small responses to these questions, producing a false negative result.

A subject who knows how the test works and recognizes the relevant and control questions may practice countermeasures to increase his response to the control questions. Even if he has a large response to the relevant questions, if he can succeed in making his response to the control questions even larger, a deceptive subject can be found nondeceptive. Countermeasures may be psychological, such as imagining fear-inducing situations, or physiological, such as biting the tongue to cause pain and the associated arousal.

The Goal of Lie Detection: The Discovery of Truth

Unless the crime being investigated is perjury, the ultimate goal of lie detection in criminal investigations is not to detect lies, but rather to discover the truth. The important question is not whether the subject is a liar, but whether he is a murderer, or the perpetrator of some other crime.

If he is guilty, the suspect almost certainly knows it. Initially, the investigators do not. The guilty suspect knows about the crime and his role in committing it. This information is stored in his brain. He seeks to conceal this information from the investigators, and lying about it is part of this effort. Asking the subject about this knowledge, and applying methods to determine whether or not he is lying, is a means to the ultimate end of determining whether the subject did in fact commit the crime and knows it. Lie detection is fundamentally a means to detect something more critical than whether or not the subject is an honest person. Its ultimate goal is to detect something that the subject knows and the investigators do not: his role in the crime.

In other words, all techniques of lie detection, from the early measurements of Erasistratus to the modern polygraph, voice stress analysis, and fMRI, are indirect methods of truth discovery. The truth is known to the subject but concealed from the investigator. Lie detection is an indirect method to discover what that hidden truth actually is. Brain fingerprinting is a direct method to discover this truth by detecting the information stored in the brain.

Modus Operandi

BE Turvey, Forensic Solutions, LLC, Sitka, AK, USA

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Case linkage The process of determining whether there are discrete connections, or distinctive behavioral factors, between two or more previously unrelated cases by means of crime scene analysis, including the examination of offender MO and signature.

Interrupted/incomplete offense One that does not contain enough MO behaviors to complete the offense.

Modus operandi (MO) A Latin term that means method of operating. It refers to the manner in which a crime has been committed.

Motive The emotional, psychological, and material needs that impel and are satisfied by behavior.

Offense gone wrong One that contains unintentional, unplanned MO behaviors that increase the offender's risk or criminal status.

X-factor Any unknown or unplanned influence that can affect crime scene behavior during an offense.

Modus operandi (MO) is a Latin term that means method of operating. It refers to the manner in which a crime has been committed. It is comprised of acts that are necessary to commit a crime, and any related choices made by an offender.

A Short History

Law enforcement has long held to the belief that understanding the methods and techniques criminals use to commit crime is the best way to investigate, identify, and ultimately apprehend them. This has traditionally required that the best detectives become living encyclopedias of criminal cases and behaviors. It has also demanded that they learn to utilize the knowledge and experience of known criminals to inform their investigative strategy.

Knowledge of Criminal Methods

In 1809, the French demonstrated a strong belief in this approach to criminal investigation through their faith in a former convict named Eugene Vidocq. He had been working as a police spy and was assigned by the government to form a *Brigade de Sûreté*. He organized and led this group of detectives, mostly former criminals themselves.

Within their first year, Vidocq and his men had made more than 750 arrests. However, they were paid based on the number of criminals that they apprehended (a common practice at the time). This led some to believe this approach was a perfect solution to the local criminal problem; Vidocq and his detectives understood how criminals operated, had insights into their habits and methods of operation, and were putting that knowledge to work for the good of the state. However, this led others to suspect that they committed many of the crimes themselves and then framed known criminals or detractors in order to close out the cases.

In 1832, Vidocq was removed from office on the charge of instigating a crime for the purpose of uncovering it. Despite this, Vidocq appears to enjoy a favorable historical place as the

first and very successful chief of the French Sûreté Nationale. Whether Vidocq was a master detective or merely continued his criminal career through the Sûreté, a philosophy of criminal investigation emerged: To understand criminals, to develop competent investigative strategies, to link their crimes, and to successfully apprehend them, detectives need to understand very intimately the particular methods criminals used to commit their crimes.

This investigative philosophy survives on an international level, in one form or another, to the present day. For example, when the United States Secret Service began in 1865, to suppress counterfeit currency, its staff consisted partly of former counterfeiters. Over the years, they have continued to employ the services of (ex)criminal consultants. They are not unique. Law enforcement agencies around the world still use criminal informants (paid and otherwise) as a necessary means to gain access to, and knowledge of, ongoing criminal activity, the methods of particular criminals and criminal networks, and information 'on the street.'

The Atcherley Modus Operandi System

By the late 1800s, major police departments developed and maintained 'MO files' on many suspects and criminal. These were essentially file cards or booking sheets that contained basic identifying information such as name, date of birth, descriptive physical characteristics, and information about any scars or tattoos. In some cases, a photograph might also have been attached. These files soon grew to contain information regarding criminal aliases, criminal history, and criminal affiliations (e.g., gangs, organizations, and known criminal associates). However, there was no formal or orderly system of offender MO classification – just information on a card that detectives might or might not bother to read.

In 1913, Major Lewellyn W. Atcherley, of the West Riding Yorkshire Constabulary in England, published a 10-point system for classifying offender MO behavior that he had developed and refined over the decades. His groundbreaking handbook was titled *Modus Operandi: Criminal Investigation and*

Detection, and it recommended scrupulous documentation and examination of the following features in every case:

1. *Classword*: the nearest possible description of the victim (e.g., person or property) attacked. If a person, what occupation? If a premises, what specific kind?
2. *Entry*: the actual point of entry to the property where the crime occurred.
3. *Means*: the actual method of entry. How did they get to the point of entry, and what tools did they use (e.g., ladders, adjacent properties, ropes, keys, and crowbars).
4. *Object*: the motive and intent of the crime, and the intended target (e.g., person or property).
5. *Time*: the actual time of the offense – not just the hours it occurred, but during which period of time (e.g., weekend, during church hours, while the occupants of a dwelling were home or away).
6. *Style*: the actual or pretended occupation of the offender during the offense; not to be confused with the offender's noncriminal trade (however, style and trade may be the same for opportunistic offenders). Sometimes the style is a presumed identity or occupation, sometimes it is the offender's actual identity or occupation, and sometimes it is entirely fabricated.
7. *Tale*: the statement made by the offender to cover their tracks – their alibi.
8. *Pal*: the nature and role of accomplices, if any.
9. *Transport*: the means with which the offender arrived at and departed from the scene of the crime (e.g., by foot, by vehicle, or by public transportation).
10. *Trademark*: extraordinary acts not associated with the object of the crime (e.g., sleeping in a bed, eating food, destroying clothing or furniture, or shaving).

Atcherley believed that individual professional criminal MOs could often be found to have a distinctive 'trademark.' Here he was referring to what would ultimately come to be known as *signature behavior*: acts committed by an offender that are not necessary to commit the crime but that suggest the psychological or emotional needs of that offender.

The Atcherley system was widely adopted by law enforcement agencies in England, and came to United States by way of August Vollmer (the first chief of police in Berkeley, California, and the leading figure behind early efforts to professionalize and modernize law enforcement training and criminal justice education in the United States). Vollmer argued that no professional police department would be without an organized system of documenting and classifying criminal MO. He explained that professional criminals were migratory; therefore, a need existed to systematically classify and organize their methods of operation, use this system for identification purposes when the offender was unknown, and communicate this information to other agencies effectively. He subsequently revised the Atcherley MO system and published it for use in 1920.

Owing to the efforts of Vollmer, who was also inspired by the publications of the Austrian jurist Dr Hans Gross on the subjects of criminal investigation, forensic science, and MO analysis, the concept of MO classification and analysis soon became foundational to forensic and investigative literature. Though advances have been made in technology, any modern development and utility of MO as an investigative concept is

based largely in classification systems that were originally set forth in Atcherley's 1913 handbook. It remains a valuable touchstone to this day.

The Utility of MO Analysis

A criminal's MO is made up of choices and behaviors that are intended to assist in their completion of the crime. It is, however, separate from the concept of motive (the emotional, psychological, and material needs that impel and are satisfied by behavior). The collection, storage, and examination of MO information, whether on arrest cards or in computer databases, has traditionally been investigatively relevant for the following reasons:

- investigative linkage of unsolved cases by MO
- suspect identification by comparing known criminal MO with the MO evidence in unsolved cases
- routine comparison of arrestee MO with the MO evidence in unsolved cases
- development of investigative leads or suspect identity in unsolved cases by virtue of accumulating MO information
- suspect prioritization or elimination
- clearance of unsolved cases

MO analysis is also an important aspect of criminal profiling. Using profiling techniques, it helps provide an array of information about the offender. This includes the involvement of criminal choices, procedures, or techniques that can be characteristic of, or reflective of, the following:

- A particular discipline, trade, skill, profession, or area of knowledge, criminal and noncriminal;
- knowledge particular to the victim, suggesting surveillance, contact, or a prior relationship (or the absence of these); and
- knowledge particular to a crime scene, suggesting surveillance, contact, or intimate familiarity (or the absence of these).

Elements of MO

As already established, an offender's MO behavior is functional in nature. It is comprised of learned behaviors that can evolve and develop over time. It can be refined as an offender becomes more experienced, sophisticated, and confident. It can also become less competent and skilled over time, decompensating by virtue of a deteriorating mental state or increased use of controlled substances. MO behaviors most often serve (or fail to serve) one or more of three general purposes:

1. *Protection of offender identity*: for example, wearing a mask during a daytime bank robbery, covering a victim's eyes during a rape, wearing gloves during a burglary, killing a witness to any of the above, and staging the crime scene.
2. *Successful completion of the crime*: for example, targeting and acquiring the victim, using a gag to silence a victim, using a weapon to control a victim, making a list of potential victims with pertinent information, and using a gun to kill the victim.

3. *Facilitation of offender escape*: for example, use of a stolen vehicle during the commission of a crime, disposal of a vehicle after the commission of a crime, and tying up/knocking out victims to prevent their escape and hamper their attempts to get help.

General elements of MO can include crime scene characteristics such as, but not limited to, the following:

- number of offenders
- amount of planning before a crime
- offense location selected
- route taken to offense location
- victim selection (when functional and not fantasy oriented)
- preoffense surveillance of a crime scene(s) or victim
- involvement of a victim during a crime (non-fantasy-related)
- use of a weapon during a crime
- use of restraints to control the victim during a crime
- nature and extent of injuries to the victim
- method of killing the victim
- nature and extent of precautionary acts
- location and position of the victim's clothing
- location and position of the victim's body
- items taken from victim or crime scene(s) for profit or to prevent identification
- method of transportation to and from the crime scene(s)
- direction of escape/route taken from offense location

It is important to note that an offender's MO can be an act or a failure to act. Common examples of failure to act include not using a condom during a sexual assault, not using a firearm during the commission of a robbery, and not killing witnesses during the commission of a home invasion burglary. These are all choices that an offender makes, whether by action or omission.

Influences on MO

An offender's MO behaviors are learned, and by extension they are dynamic and malleable. This is because MO is affected by time and can change as the offender learns or deteriorates. An offender's MO is therefore a function of both fortifying and destabilizing factors.

Fortifying Factors

Offenders may realize that some of the choices they make during a crime are more proficient and effective than others. They may subsequently repeat them in future offenses, becoming more skillful as well as strengthening or fortifying their MO. Over the course of a criminal career, offenders may also incorporate choices that unintentionally reveal something about their identity, character, or experience. Common ways that offenders may learn how to commit crimes more skillfully, evade capture, and conceal their identity (i.e., fortifying factors) include, but are certainly not limited to, those listed here.

Educational and technical materials

Until they are captured and convicted, criminals have equal access to the same learning opportunities as any other citizen.

Professional journals, college courses, textbooks, and other educationally oriented material available at a bookstore, public library, or via that Internet can provide active offenders with knowledge that is useful in refining their particular MO.

Trade or professional experience

Offenders may have been, or may currently be, employed in trades or professions that utilize special knowledge or that require proficiency with specialized techniques (e.g., electrician, plumber, telephone company, software design, military, law enforcement, and pilot). Such specialized knowledge may find its way into an offender's MO and be reflected in the offense. The offense may also reflect an opportunity created by the offender's profession, by virtue of time, place, and victim availability.

Criminal experience and confidence

As offenders commit more of the same type of crime, they can become more proficient at it. They may act more confidently, be able to handle the unexpected more smoothly (or even be prepared for it), or they may have tailored their precautionary acts to the type of criminal activity they expect to engage in.

Contact with the criminal justice system

Being arrested just once may teach an offender an invaluable lesson about how to avoid detection by law enforcement in the future. Furthermore, and ironically, a prison term in the United States is referred to by some in both law enforcement and the criminal population as 'going to college.' This is because in prison, younger and less experienced offenders have the opportunity to network with older and more experienced offenders who have already accumulated a great deal of criminal knowledge. Consequently, a prison term of only a few years has the potential to advance an offender's knowledge and skill level far beyond their original MO. Once released, they may take this 'education' and embark on criminal enterprises that previously would have been beyond his or her ability.

The media

Some offenders monitor investigations into crimes by paying close attention to media accounts in the newspapers and on television. Not only may information relating to a case provide an offender with insight into the need for future precautionary acts, but it may also provide unrelated offenders with adequate information to 'copycat' a particular series and deflect investigative attention.

Destabilizing Factors

MO can also deteriorate over time and become less skillful, less competent, more careless, and more irrational. Common mechanisms that cause or contribute to MO destabilization over time include, but are certainly not limited to:

- deteriorating mental state
- use of controlled substances
- overconfidence, which can lead to carelessness
- offender mood (e.g., agitated, excited, or otherwise distracted)
- involvement of unskilled or destabilized accomplices

X-Factors

An *X-factor* is any unknown or unplanned influence that can affect crime scene behavior during an offense. The successful completion of a crime, from an offender's perspective, depends on events conforming to expectations. Under real-life conditions, crime scenes, victims, and other extrinsic influences do not always conform to an offender's plans. This includes, among many possibilities,

- weapon malfunction
- unexpected witnesses
- victim preparedness/response (e.g., Mace, a victim trained in self-defense)
- ineffective method of killing or control, resulting in unplanned victim survival or death
- vehicle malfunctions (e.g., faulty engine, out of gas, or flat tire)
- increased security measures at preselected scene
- unreliable accomplices

The presence of any number of X-factors may force the offender to improvise or to make a hasty retreat, resulting in an *interrupted/incomplete offense* or even an *offense gone wrong*.

An *interrupted/incomplete offense* is one that does not contain enough MO behaviors to complete the offense. An incomplete crime might include the following: A victim, instead of being easy prey, turns around and kicks the offender in the groin. The offender may be stunned and limp away, or the victim may create an opportunity to flee the scene. Or, during the attack, a passerby might unwittingly witness the offender, who may then flee the scene. The offender may also choose to walk away from the offense for any reason. Either way, the event would not have included the full potential range of offender MO behaviors and would therefore be incomplete.

An *offense gone wrong* is one that contains unintentional, unplanned MO behavior, which increases the offender's risk or criminal status. An event gone wrong might include the following: The offender might accidentally use too much force, or the victim's response might be too violent for the offender and the offender's control-oriented choking could result in the victim's death. This turn of events can transform a serial rape investigation into a homicide investigation, increasing the offender's criminal status.

Uniqueness and Reliability

MO is often used as a tool in the investigative task of *case linkage*, which is the process of determining whether there are discrete connections, or distinctive behavioral factors, between two or more previously unrelated cases by means of crime scene analysis – including the examination of offender MO and signature. However, it is often unsuited for forensic (aka courtroom) purposes.

MO is dynamic and malleable – suffering from all manner of influences over time and circumstance. First, as explained in Weston and Wells (1974, p. 110), not all criminals have a particular MO, but some of them have distinctive enough methods to justify making investigative note of it. Second, within a given series of related crimes, each crime scene is

different; each victim responds differently from others; and even individual offenders are often in a different mood or frame of mind each time they commit a crime. Consequently, MO is not consistently comprised of behaviors that are necessarily distinctive or even unique to a particular offender; their crimes will often unfold differently each time, even when committed with the same motive, intent, and methods.

Given these realities, while helpful in the investigative task of case linkage, MO is often insufficiently reliable to address the issue of criminal identity in the courtroom. That is to say, MO is best used to help guide investigators to more certain evidence and keep their efforts on course. It should not generally be confused as conclusive evidence suggestive of offender identity when two or more cases are being compared, and certainly not in a legal context.

There have been some attempts to database criminal MO behavior with computer software, such as the FBI's Violent Criminal Apprehension Program (ViCAP) and a similar Canadian effort by the RCMP, the Violent Crime Linkage Analysis System (ViCLAS). However, both systems are only as reliable as the case data that is entered into them by police investigators and the later viability of searches performed by law enforcement analysts. Problems have been identified in both areas. Additionally, many law enforcement investigators find the process of submitting a case to either system time consuming and often complain about a lack of results – to the point that ViCLAS has been all but discontinued in Australia. Until such time as these databases are shown to be demonstrably reliable and representative by research efforts from independent examiners, the results of any searches remain investigatively relevant but generally inadmissible as evidence of offender identity in court.

This article has been adapted from Turvey (2011).

Glossary

Case linkage The process of determining whether there are discrete connections, or distinctive behavioral factors, between two or more previously unrelated cases by means of crime scene analysis – including the examination of offender MO and signature.

Lovemap A developmental representation or template in the mind and in the brain depicting the idealized lover and the idealized program of sexueroetic activity projected in imagery or actually engaged in with that lover.

MO behaviors Actions and decisions intended to assist in the completion of a crime.

Modus operandi (MO) A Latin term that means method of operating. It refers to the manner in which a crime has been committed.

Motive The emotional, psychological, and material needs that impel and are satisfied by behavior.

Offender signature Offender signature refers to the pattern or cluster of MO behaviors, signature behaviors, and motivation-oriented behaviors that occur within an offense or across a series of related offenses.

Psychodynamics The manner in which conscious and subconscious drives, emotions, and desires combine to determine personality and motivation.

Signature behaviors Signature behaviors are those acts committed by an offender that are not necessary to commit the crime, but rather suggest psychological or emotional needs.

Offender signature refers to the pattern or cluster of modus operandi (MO) behaviors, signature behaviors, and motive-oriented behaviors that occur within an offense or across a series of related offenses. *MO behaviors* are actions and decisions that are intended to assist in the completion of a crime. By contrast, *signature behaviors* are those acts committed by an offender that are not necessary to commit the crime, but rather suggest psychological or emotional needs. An offender's signature behaviors are not functional in nature. They reflect psychodynamic relationships and predispositions that are generally more stable and enduring over time than those evident in their MO. The pattern of behaviors may be unique to a particular offender and may be used to distinguish between crime scenes and potentially between offenders. However, this is infrequently the case.

Origins

Adapted from the investigative concept of a criminal 'trademark,' the term *signature* came to be used in legal parlance to refer to an unusual or distinctive criminal MO. Expert testimony regarding this kind of evidence is often proffered (and sometimes admitted) in court to link cases for the purposes of showing offender identity, criminal propensity, to demonstrate motive. It may also be used to help demonstrate the need for joining (or separating) cases at trial. As provided in early court decisions, and legal references as far back as *McCormick on Evidence* from 1954, MO evidence is only admissible when the behavioral pattern is unusual and distinctive, like a signature. Repetition of similar behaviors is not enough.

However, MO behaviors frequently change, are susceptible to a variety of influences, and are not always that distinctive.

In other words, MO behaviors generally do not, by themselves, provide the distinctiveness of a signature. So while early criminologists and jurists inappropriately conflated the concepts of MO and signature, the modern literature recognizes that they are very different. To understand these differences, a basic understanding and consideration of offender psychodynamics is required.

Offender Psychodynamics

Psychodynamics is a term that refers to how conscious and subconscious drives, emotions, and desires combine to determine personality and motivation. To understand offender psychodynamics, we must start with accepting that not all offenders are the same. They each have different histories, different tastes, and different needs. Therefore, similar behaviors committed under similar circumstances by different offenders will not necessarily be for identical or even similar motivations.

According to the American psychologist Dr. John Money, the explanation for this behavioral–motivational distinctiveness is found in the mind's eye of the offender: each maintains a pattern of specific behaviors and subsequent associated feelings that is referred to as a *lovemap*. This is a term that Dr. Money developed to describe an idealized scene, person, or program of activities that satisfy the particular emotional and psychological needs of an offender.

Lovemaps, specialized needs, or fantasies develop in all people (not just criminals) as a part of the natural process of human development and can subsequently be affected by both biological and environmental factors. The development of an offender's signature behavior necessarily follows a parallel path

with sexual and emotional development. As a lovemap develops and related personality is shaped, the behaviors necessary to achieve individual needs are identified, incorporated, and developed. For some, the result may be a healthy expression manifested in nurturing and intimacy-seeking relationships. For others, at the more distant end of the continuum, the result may be the incorporation and development of antisocial and even criminal behaviors.

Dr. Money theorized that criminal behaviors result when the human developmental process is derailed and a person is able to make pleasurable associations with violent or otherwise criminal activity. These associations, varied and evolving over time, amount to a behavioral distinctiveness in the way that an individual offender seeks to satisfy emotional or psychological needs during the commission of a crime such as rape, homicide, arson, and other similar or serial offenses.

As an offender's fantasies develop over time, so does the need to live out those fantasies. When a violent or predatory fantasy is subsequently acted out, the act itself fuels the fantasy in the mind of the offender and causes it to evolve. The process is complementary and can facilitate the evolution of fantasy, signature behaviors, and overall offender signature over time.

Behavioral Consistency Theory

The *behavioral consistency theory* suggests that the same criminal will behave in relatively the same way across offenses. Some researchers have hypothesized that there is both 'offender behavioral consistency' and 'offender behavioral distinctiveness,' which may be used in linkage analysis efforts to identify "crimes suspected of being committed by the same perpetrator on the basis of behavioral similarity." The assumptions of these researchers ignore two of the more important axioms of behavioral evidence analysis:

1. Different offenders do similar things for different reasons (this is known as the *principle of behavioral variance*).
2. Individual offender behaviors are multidetermined; they can be the result of multiple offender motivations and multiple external influences (this is known as the *principle of multidetermination*).

This is not to suggest that case linkage efforts using offender signature are futile because of the complex and dynamic nature of human behavior. Rather, that case linkage is not always possible, and it is rarely certain. Oversimplifying the problem of interpretation with assumptions that ignore the principles of behavioral evidence analysis does not move us closer to accurate case linkage efforts – it moves us further away.

This position directly contradicts the *offender (behavioral) consistency hypothesis* originally proposed by Canter as an underlying assumption of profiling methods employed by investigative psychologists in their research. Canter's hypothesis predicts that offenders will show consistency (or similarity) in their criminal behavior across their series of crimes. Unfortunately, not only can behavioral manifestations of MO and signature vary across a series, but also the series under examination may be only one type of crime among many that are being committed by an offender. An offender responsible for a series of rapes may also be responsible for a series of burglaries. An offender responsible for

a series of homicides may also be responsible for a parallel series of rapes, robberies, or thefts. Offenders with such multiple criminal pathways are by no means rare, yet scholars tend to lump and study offenders into fixed groups as though criminal diversification does not happen at all.

Recognizing Signature Behavior

It should be noted that the mere repetition of a given behavior or across multiple offenses is not enough to make it signature-oriented. It may simply be a repeated part of the offender's MO. Generally, the following will be true of a signature behavior:

1. Takes extra time to complete, beyond mere functional MO behavior
2. Unnecessary for the completion of the crime
3. Involves an expression of a need or emotion
4. May involve an expression of fantasy

If a behavior satisfies these criteria, then it is a signature behavior – that is to say, it is related to the offender's psychological and emotional needs (fantasy and motive) rather than functional crime-related needs.

Active and Passive Signature Behaviors

There are two types of signature behaviors: *active* and *passive*. *Active signature behaviors* are conscious or deliberate acts committed by the offender. They result from an offender who is in control and intends to leave a specific psychological impression or to satisfy a particular emotional need. Examples can include, but are not limited to,

- Specific and repeated victim type
- Specific and repeated constellation of injuries to body
- Notes left at the scene
- Specific and repeated weapons that go beyond mere function
- Specific and repeated ligature/binding type or configuration

Active signature behavior represents a clear message from the offender; the offender is aware it is being sent and it is meant to be recognized and understood.

Passive signature behaviors are incidental in nature. They result from an offender who is not in control and unintentionally leaves a particular psychological impression. Examples can include, but are not limited to,

- Overkill or brutal levels of force
- Obsessive/compulsive behavior (e.g., stalking and harassment)
- Jealous or self-deprecating language or scripting

Passive signature behavior is the result of offenders that are out of control of their emotions and are unaware that their feeling or needs may be revealed by what they are doing.

Limiting Factors

There are important limitations to the concept of offender signature that require attention. An offender's signature pattern

is sometimes referred to inappropriately as a 'calling card' or a 'trademark.' These terms evoke the vision of a static, inflexible, indelible mark or psychological imprint left behind at the crime scene. Something that is consistently present and easily discerned. While this is a regular feature of crime-related films, television, and novels, such evidence is rare in real life.

Many serial or predatory offenders do not have a need to engage in personal expressions of emotion that are distinct to their individually formed personality. Furthermore, despite the distinctiveness of an offender signature, which is a result of many psychodynamic variables, it is not truly appropriate to state that two crime scenes related by signature alone are psychologically 'identical.'

For example, the term *match* may be used to suggest shared characteristics between two things. But by their very nature, crime scenes and crime scene behaviors cannot precisely be the same across offenses, even when the same offender is responsible for them. Not only are the locations likely to be different, but also the victims are most certainly different people with their own responses to offender behaviors that will in turn influence the offender's behavioral expressions, both MO and signature-oriented.

One of the other primary reasons for the lack of absolute certainty in interpreting signature behaviors as unique to a specific offender is the subjectivity of the interpretation itself. While offenders may be psychologically distinct, forensic examiners cannot see through the eyes of an offender with perfect, objective clarity. They can show the most likely perspectives and needs of the offender by demonstrating a strong convergence of the physical and behavioral evidence, but they cannot go so far as to call it a 'psychological fingerprint.'

Additionally, when asked to make inferences about offender signature, forensic examiners may not have all the facts in the case, or they may be operating with flawed investigative assumptions. Consequently, a thorough forensic examination of offender signature will consider the following factors:

- Whether the amount of behavioral evidence is sufficient to make an interpretation of offender signature (e.g., Was there a competent crime scene reconstruction performed? Were the forensic protocols that the reconstruction is based on adequate? Was evidence of wound patterns lost due to bodily decay?)
- Whether the amount of behavioral evidence is fully representative of the offender's needs (e.g., Is there evidence of interruption during the crime? Did the offender have the time to do all of the things that he or she felt was important?)
- Whether the behavioral evidence suggests a signature that is part of an escalation or evolution in an offender's fantasy continuum or whether the offender signature appears to be relatively fixed over time

As a consequence of these limitations, it may not always be possible to link or unlink cases using offender signature, for the following reasons:

- An offender may not always leave behind evidence of signature behaviors (e.g., interrupted offense, incomplete offense, or limiting x-factors).
- An offender may engage in precautionary acts that conceal the evidence of signature behaviors (burning evidence,

removing unknown fantasy items from the crime scene, staging the crime scene, etc.).

- Evidence of offender behavior may be lost, overlooked, or destroyed by forensic personnel and criminal investigators.

Case Linkage: Offender Signature in Court

Case linkage is the process of determining whether there are discrete connections, or distinctive behavioral factors, between two or more previously unrelated cases by means of crime scene analysis – including the examination of offender MO and signature. This kind of analysis is done in both investigative and forensic contexts.

When the physical evidence in a given case is insufficient, or when the law allows it, behavioral evidence (e.g., offender signature) may be employed as a means of addressing the question of case linkage.

Legal Rulings

In California, for example, some legislation and legal rulings have led to the more frequent courtroom use of behavioral evidence relating to offender MO and signature. Specifically, in cases involving alleged multiple offenses committed on separate occasions (i.e., serial offenses, most often involving kidnapping, arson, rape, and homicide), the issue of linking cases by examining offender behavior becomes central. Below are three issues common to forensic casework, necessitating case linkage efforts involving offender signature.

Common scheme or plan: Under California Penal Code section 1101(b) of the Evidence Code, evidence of both charged and uncharged misconduct (cases where an offender is suspected, but no charges have been filed) may be admitted for the purpose of demonstrating a common plan, scheme, or design if the offenses are sufficiently similar (*California v. Ewoldt*, 1994).

Ewoldt does state that evidence of prior uncharged sexual acts is admissible at a subsequent trial for sexual offenses, in order to show a common design or plan on the part of the defendant. However, the court also found that 'evidence of uncharged misconduct' may only be admissible if it is 'sufficiently similar' to the charged offense "to support the inference that they are manifestations of a common design or plan." No concrete definition of 'sufficiently similar' has been established by the courts.

Connected together in their commission: Under California Penal Code section 790 of the Evidence Code, multiple offenses committed by the same offender in multiple counties may be consolidated for trial in a single county (thus introducing a highly prejudicial element) if it can be shown that the crimes are properly joinable, and that they are connected together in their commission.

No concrete definition of 'properly joinable' or 'connected together in their commission' has been established by the courts.

Propensity: California Penal Code section 1108 was more recently added to provide a specific exception to 1101 in sex crime cases where a person is charged with a sexual offense and the prosecution wants to offer evidence of prior, or other sexual

offenses to show a propensity to commit the charged offense. This is a special exception to single out 'sexual predators.'

Many states have similar if not identical legal statutes and related decisions regarding admissibility. According to *Ewoldt* and *Balcom*: "The greatest degree of similarity is required for evidence of uncharged misconduct to be relevant to prove identity." (*California v. Ewoldt*, 1994; *California v. Balcom*, 1994). Furthermore, "For identity to be established, the uncharged misconduct and the charged offense must share common features that are sufficiently distinctive so as to support the inference that the same person committed both acts. 'The pattern and the characteristics of the crimes must be so unusual and distinctive as to be like a signature,' (McCormick on Evidence, 4th edn., 1992); *California v. Ewoldt*, 1994).

Despite these stringent legal requirements, there is no evidence or research to suggest that behavioral evidence alone may be used like fingerprints or DNA with respect to determining with any certainty that the same person must be responsible for two or more crimes. Furthermore, while there may be general or thematic similarities between some cases, the dissimilarities between cases are of greater weight and importance to rendering final linkage conclusions. Linkage analysis efforts that fail to account for dissimilarities, focusing only on similarities, should be considered inadequate at best, if not biased.

Expressing Case Linkage Results

To enable expression of behaviorally oriented case linkage findings in a manner that is useful to investigators and the court but does not mislead with respect to certainty, a series of progressive confidence statements may be used:

- Behavioral dissimilarity
- An investigative linkage
- Behavioral commonality
- A probative link

Behavioral dissimilarity means that behavioral factors have been compared and they are dissimilar. For example, two homicide cases are presented. One involves the use of a handgun with a single shot to the victim's head. The other involves manual strangulation. The two cases have evidence of behavioral dissimilarity in the use of a weapon. It is important to note that behavioral dissimilarities must be analyzed in the context of the entire crime and in relation to all offender behavior. The existence of dissimilar behavioral factors between crimes does not necessarily refute a linkage. Take, for example, an offender who engages in unique signature behaviors with multiple victims of different risk or exposure levels. Victim risk and exposure in this case is a behavioral dissimilarity, but the different levels may reflect changes in the offender's MO behavior over time and across offenses. Therefore, behavioral dissimilarities may exist within crimes that evidence a *probative link*.

An *investigative linkage* is a general class connection between one or more cases that serve to inform the allocation of investigative resources (i.e., in terms of behavior, general, or opportunistic circumstances of the offense; general similarities in MO; and similar signature aspects evidenced by signature

behaviors that are perhaps dissimilar). Such a link, as the name suggests, requires further investigation. It is not conclusive. An example of an investigative link would be finding two women murdered in their homes, in generally the same fashion, in the same community, over the course of a year. The general description is of interest, and resources should be applied to investigate further possible connections, as may be found in victimology, MO, signature behavior, and the physical evidence. During any one of these examinations, a more certain linkage may be established or refuted. If more information is not available, it must be remembered that an investigative linkage is not sufficient to suggest a *behavioral commonality*, let alone a *probative link*.

A *behavioral commonality* is present when behavioral factors have been compared and they are similar but not *unique*. For example, two convenience robberies occur in broad daylight. Both involve a 0.357-magnum handgun. Both involve an offender wearing a mask. These robberies evidence behavioral commonalities with respect to time of day, precautionary acts, location type, use of weapon, and even motive. However, this robbery pattern is not unique, especially in large urban areas.

A *probative link* is evidenced by either a unique offender *behavior* or a unique *offender signature* that is shared across two or more cases, with limited behavioral dissimilarity. It is a connection that is sufficiently distinctive to support the inference that the same person is responsible. Physical evidence, such as certain kinds of DNA, may also provide a probative link – and must therefore not be ignored unless intentionally set aside for court purposes.

When determining whether a unique offender signature exists between two or more crimes, the behavioral dissimilarities are also of importance. If significant behavioral dissimilarity exists between crimes that cannot be explained by evolving or devolving MO behavior, a probative link should not be cited in the final case linkage analysis.

Glossary

Behavioral forensic science A subfield of forensic science that focuses on how to think about and do work at the intersection of the criminal justice and mental health systems.

Clinical behavioral forensic science The branch of behavioral forensic science that emphasizes the application of psychological assessments, diagnostics, and treatments to various offender/victim populations and within diverse crime and justice contexts.

Forensic psychology The academic and educational arena in which behavioral forensic science is learned and practiced.

Law-psychology behavioral forensic science The branch of behavioral forensic science that emphasizes the application of evidence-based law and social sciences to various offender/victim populations and within diverse crime and justice contexts.

Law-psychology-justice behavioral forensic science The branch of behavioral forensic science that emphasizes the application of philosophy and ethical principles to various offender/victim populations and within diverse crime and justice contexts.

Introduction

The behavioral forensic science field has grown dramatically in the past several decades. This growth represents an effort to meet the increasing demands of the criminal justice system and its police, court, and correctional apparatuses and respective work forces. Addressing these often technical, clinically challenging, and policy-oriented demands requires an appreciation for psychological insights and values (an understanding of behavior) and a grasp of victim-offender processing, treatment, and community reentry (an understanding of forensics). The academic subfield that typically attends to the issues located at this intersection is forensic psychology. These issues extend to various levels of investigation and include individual, group, institutional, and societal domains of inquiry and analysis.

Although forensic psychology emerged in the early 1900s, the American Psychological Association did not formally recognize it as a specialization until 2001. Consequently, the contours of this subfield have yet to be fully agreed upon or even delineated. Some investigators broadly describe it as any application of psychological research, methods, theory, and practice to a task faced by the legal system. Despite the absence of consensus on what forensic psychology conceptually means (including the expansiveness of its scope and focus), it has quickly established itself as one of the leading academic subdisciplines in psychology.

In order to prepare researchers and practitioners for careers in forensic psychology, a number of graduate training models have been developed. These instructional frameworks incorporate a diverse range of evidence-based scientific approaches into their service-based and related practices. However, given the burgeoning pace of the field's development, the robustness of each model remains a source of ongoing theoretical and empirical investigation.

In what follows, three educational philosophies for thinking about and doing forensic psychology (i.e., behavioral forensic science) are described. These models include the clinical,

the law-psychology, and the law-psychology-justice approaches. Several distinguishing facets of the models are described, including their respective didactic frameworks, definition of the client-practitioner relationship, preferred method of intervention, and understanding of the psychologist-organization relationship. A proposed agenda for future directions concludes the essay, mindful of the three educational philosophies under review.

Education and Training in Forensic Psychology

The Clinical Approach to Thinking About and Doing Behavioral Forensic Science

The clinical approach principally addresses criminal and delinquent behavior. Clinical practitioners offer police departments, judicial officials, and correctional administrations sound psychotherapeutically based solutions to problems that they frequently encounter within their respective agencies, courtrooms, prisons, and treatment centers. As such, these mental health professionals provide clinically grounded insight regarding adult and juvenile criminal pathology, whatever its manifestations. Specifically, as scientifically trained practitioners, police, criminal, and correctional psychologists meet the system's behavioral forensic science needs through victim and offender evaluation, diagnosis, and treatment. These interventions represent forms of institutional and community assistance.

The didactic framework of the clinical approach to behavioral forensic science offers graduate students a traditional course of study, resulting in the award of either the Ph.D. (scholar-practitioner) or the Psy.D. (practitioner-scholar) degree. The Ph.D. curriculum includes classroom instruction followed by a predoctoral (and often a postdoctoral) internship. The Psy.D. curriculum implements elements of the predoctoral internship experience into the classroom training and may include a postdoctoral internship. In both instances, students receive instruction on standard cognate areas of study,

including testing and assessment, therapy and treatment, and research methods and statistics. While the pedagogical strategies leading to each degree are somewhat distinct, both didactic frameworks within the clinical orientation primarily focus on evidence-based coursework and related instructional training. Once these requirements are completed, dissertation supervision, independent research, faculty mentoring, and field placements provide students with *real-world* experience in forensic psychology.

At the core of the clinical approach is the relationship between the offender/client and the practitioner. An effective client–practitioner relationship is imperative to an understanding of crime and delinquency and the psychopathologies that contribute to criminal behavior. From the clinical perspective, the therapist is viewed as a member of the mental health community and is present to the client (the offender), regardless of degree, type, and frequency of crime. Thus, the offender/client is perceived as an average citizen who requires assistance from a mental health professional, including various forms of clinical intervention. Typically, such evaluations and treatments are court ordered. Although practitioners may be required to conduct assessments, delineate a diagnosis, and provide therapy, their essential purpose is to draw attention to the psychological state of the offender/patient in order to ensure that mental health problems are properly identified and addressed. The clinical approach adopts a similar kind of client–practitioner relationship with victims of crime whose trauma and recovery issues also necessitate evaluation, diagnostics, and treatment.

In order to properly evaluate an individual, the clinical approach to behavioral forensic science includes a broad range of projective, intellectual, and personality assessment tools. Additionally, a host of therapeutic approaches and prevention/treatment techniques are employed. Because valid and reliable instruments from all three types of testing are used to reach context-specific mental health determinations, proponents of the clinical orientation contend that its interventions and recommendations amount to scientifically sound behavioral forensic practice.

Given that these professionals are principally concerned for the client's mental health and well-being, their relationship with police precincts, court agencies, correctional facilities, and community-based programs is often somewhat detached. Indeed, clinical specialists are commonly perceived as 'outsiders' within the organizations in which they work. As such, in order to best serve the needs of their patients, practitioners schooled in the clinical approach determine intervention strategies that law enforcement officials, judicial administrators, correctional managers, and treatment centers can employ within their own organizations.

One example in which clinically trained practitioners are utilized within the system is in the administration of competency evaluations involving the death penalty. As requested by the courts, clinicians seek to determine two critical findings – does the defendant have the capacity to understand, in general, the death penalty and its effect should it be imposed; and can the defendant coherently communicate relevant facts in mitigation to his or her attorney. If the offender is found incompetent, the forensic psychologist will dispense treatment (recommend drug therapy) in order to restore one's competency such that the

execution can then proceed. The role of the clinician in conducting competency for execution evaluations continues to be fiercely debated among those within and outside of the behavioral forensic science field.

The Law–Psychology Approach to Thinking About and Doing Behavioral Forensic Science

Another educational model within the realm of behavioral forensic science is the law–psychology approach. While its clinical counterpart rigorously emphasizes empirically based inquiry and solutions, this didactic strategy additionally incorporates the study of law and legal decision making into its understanding of forensic psychology. In other words, beyond scientifically examining individual behavior, the pedagogical aim is to produce legally informed clinicians. Consequently, students are cross-trained in the two distinct disciplines. The overall instruction is designed primarily for professionals pursuing careers in research, policy, and consultation.

In order to prepare students for careers in law and psychology, the model's educational strategy requires instruction that results in the conferral of a J.D. degree and a Ph.D. or Psy.D. degree in clinical psychology. Although the purpose of the curriculum is twofold, the coursework in these two disciplinary-specific areas is typically offered with little regard for any meaningful integration of both academic domains. That is, law and psychology curricular courses only occasionally address topics in which the interdependence of the two fields is featured such as Law and Behavioral Science. Much like the clinical model, the law and psychology didactic framework is designed to include both in-class learning and internship experience. Additionally, predoctoral practicum training is required.

The law–psychology approach is also similar to its clinical counterpart in that both ultimately seek to examine and/or treat the offender/patient's individual behavior, emphasizing ownership and responsibility for criminal wrongdoing. Advocates of this perspective assert that society's greater interests are promoted when aberrant conduct is addressed and remedied. The law–psychology approach traditionally defines the client/practitioner relationship as one in which the patient's mental health needs warrant attention and the behavioral forensic expert intervenes as this professional would for any other individual seeking assistance.

However, the law–psychology model is distinct in several important respects. Fundamentally, it establishes the legally informed clinician whose instruction/training in testing, diagnostics, therapy, and related scientific practices enables this specialist to identify empirically sourced and *court-relevant* treatment strategies. These interventions therapeutically address the patient's psychiatric condition but within the limits of what the law will allow. Second, it creates lawyer psychologists whose instruction/training in dispute resolution, law and social sciences, therapeutic jurisprudence, and related skills-based practices readies this professional to assess the effectiveness of any clinical psychological intervention mindful of various civil and criminal justice milieus and contexts for adjudication. Third, in addition to considerable grounding in forensic mental health, lawyer psychologists receive detailed exposure to legal reasoning, writing, and decision making,

as well as professional (trial) practice experience. The interventions that follow from this dual preparation intend to yield better care-oriented and solution-focused outcomes for patients whether as perpetrators or victims of crime.

The relationship between legally trained clinicians and the agencies, courts, and other facilities that solicit consultation from or otherwise employ them is somewhat attenuated. Much like the training of clinicians, lawyer psychologists often are perceived as outsiders. Indeed, while they understand the dynamics associated with the legal and the psychological systems more broadly and synthetically than traditionally trained clinicians who focus most especially on the individual patient, difficulties, nonetheless, emerge for law–psychology specialists. These difficulties relate to developing or implementing institutional interventions, mindful of organizational–cultural influences that regularly impose bureaucratic barriers. These barriers can (and often do) undermine prospects for growth and change.

In practice, professionals informed by the law–psychology model may fill several roles within the criminal justice system. For example, legally informed clinical researchers often undertake an examination of practical issues. One example is eyewitness testimony. Its more complete investigation involves a comprehension of both cognitive and legal intricacies. These experts may be called upon by prosecuting or defense attorneys to serve as forensic behavioral witnesses. When brought before a court, the specialist typically discusses the empirical evidence related to eyewitness testimony. But this testimony also includes its shortcomings, especially when used for purposes of courtroom decision making regarding various civil and criminal claims and/or disputes. These forensically sourced observations assist jury members and jurists as they assess the credibility (or even admissibility) of such expert accounts. Thus, legally informed researchers and clinicians provide useful information on scientific matters at the law–psychology nexus.

The Law–Psychology–Justice Approach to Thinking About and Doing Behavioral Forensic Science

Unlike the clinical and law–psychology approaches, the law–psychology–justice model is multidisciplinary in orientation. Its psychosocial lens is as more broadly focused as is its assessment of those dynamics that influence or coproduce the phenomena investigated within its expansive ambit. As a practical matter, the framework addresses individual, group, collectivist, and societal behavior including its civil forms (especially institutional levels of analysis) and criminal dimensions (consisting of individual responsibility and organizational accountability). Committed to citizen justice, communal well-being, and large-scale reform, those educated in this approach promote individual growth and social change through the theory and praxis of psychological jurisprudence (PJ). PJ refers to theories that depict, account for, and predict law by examining human behavior. Thus, rather than studying how judges and other legal agents within the mental health and justice systems make decisions, PJ informs judicial officials, legislators, and administrators on how they could and should make decisions, especially when guided by PJ's method of critique.

The law–psychology–justice approach is structured such that students eventually attain the Ph.D. degree. The educational philosophy is distinct from its clinical as well as law–psychology counterparts in that it relies heavily on integrative and cross-disciplinary pedagogy. Thus, in addition to the standard coursework in behavioral forensic sciences as developed by its competing models, the law–psychology–justice orientation exposes students to subject matter in sociology, organizational science, philosophy, cultural studies, and political/social theory, as well as integrative curricular offerings in psychology and law. Exposure to the overall instructional framework allows students to more completely examine and/or critique how values such as dignity, fairness, autonomy, agency, community, freedom, ethics, and the like function (or not) within systems of risk management and social control (e.g., penal, psychiatric, social welfare, and legal apparatuses).

Students earning the Ph.D. degree typically pursue positions in mental health and justice administration, community organization and leadership, human services and social welfare management, political and social activism, law and public policy, or academic research. In preparation for a career in these fields, predoctoral practicum experiences are developed that bolster didactic instruction. As an element of educational praxis (i.e., thinking about and acting on human/social justice and change), these enrichment activities help to ready graduates for the complex work demands situated within the behavioral forensic science field.

Those trained according to the law–psychology–justice model posit that each of us (i.e., as the kept or as their keepers, managers, or watchers) cannot exist apart from the structural and institutional forces or intensities to which we are connected. In other words, *captivity and risk management* affect all of our lives to varying degrees. Accordingly, professionals schooled by way of this framework seek to normatively identify and dynamically overcome the underlying conditions that nurture and sustain such *madness* for one and all. In this regard, the law–psychology–justice approach challenges extant notions of duty, responsibility, consequence, interests, violence, compassion, health, recovery, and the like. Moreover, its reformist agenda endeavors to discern how justice is defined and for whom it is served given the circumscribed (and often 'carnival-like') policies and practices emanating from the mental health, social welfare, and criminal justice systems. As a diagnosis of madness, understood as systemic pathology, this critical discernment identifies the coproductive symbolic, linguistic, material, and cultural forces (i.e., symptoms) that support harmful renditions of reality. These socially constructed 'fictions' often (and unwittingly) set limits to being (the recovering subject) and impose denials on becoming (the transforming subject). This is harm that interdependently affects us all.

The recognition of shared injury, struggle, and even deception enables the law–psychology–justice professional to cultivate a client/practitioner relationship marked by considerable inclusiveness and transparency. To be clear, the practitioner may represent the interests of individuals as well as those agencies and institutions that employ them and the greater society to which they all are inexorably bound. As such, the behavioral forensic experts' connection to and relationship with those suffering from the violence of captivity and risk management are both fluid in nature and emergent in intervention.

The intervention methods employed by law–psychology–justice specialists are directly linked to PJ theory and its ethically sourced core practices. These practices consist of commonsense justice (advancing dignity and fair-mindedness), therapeutic jurisprudence (using law as a healing agent), and restorative justice (making peace among those who offend, those victimized, and the communities that unite them). The integration of these practices grows habits of character and of caring that, when genuinely embodied and regularly examined, instantiate self-excellence or human flourishing. When exercised dynamically as virtues (e.g., living justly, benevolently, wisely, generously), the synthetic practices of PJ more humanely and communally treat the distress of the kept (those confined) and their keepers (those who confine), their managers (those who administrate confinement), and their watchers (politicians, pundits, and the public at large). This is a clinical *sociological* method for overcoming the harm of captivity, risk, and character’s devolution. This includes injury, regardless of its civil forms (e.g., courts waiving developmentally immature juveniles to the adult system found competent for trial, prisons placing psychiatrically disordered offenders in prolonged disciplinary segregation not considered cruel and unusual punishment) or criminal dimensions (setting limits to being and imposing denials on becoming for one and all).

Future Directions

The Clinical Approach

In addition to broadening coursework and training options, some leaders in the field have recommended that clinical curricula focused on cognitive, developmental, experimental, or social psychology should be available so that more students can then cultivate an expertise in one of these practice domains. For example, drawing upon a sound body of research revealing correlations between biological factors and antisocial conduct, forensic neuropsychology seeks to apply the science of brain–behavior relationships to legal decision making and courtroom practice. In order to better meet the increasing demand for these practitioners, traditional clinical curricula should be expanded to include optional instruction in the theory and methodology of this emerging and promising area. Moreover, critics within the forensic psychology field assert that by narrowly concentrating on the evaluation, diagnosis, and treatment of individual clients, nonclinical problems contributing to deviancy and delinquency are potentially overlooked by practitioners. Thus, the clinical didactic framework additionally would benefit from coursework and practice opportunities that invited students to examine how economic, environmental, social, and systemic factors contribute to a more complete understanding of offender behavior, violence and victimization, and effective programmatic responses to both.

The Law–Psychology Approach

As described previously, the law–psychology didactic framework does not include systematically integrated training in these two disciplines. Thus, coursework that squarely addresses established or emerging issues at the nexus of law and psychology should be developed. Although legally informed clinicians

may perceive themselves as insiders who provide judicial officials, correctional administrators, and other institutional-level decision makers with relevant empirical evidence, those skeptical of this model’s efficacy argue that its adherents fail to recognize that important social problems persist because of conflicting group values and competing political interests, not because the authorities lack accurate information. With this in mind, course offerings, field training, and continuing education consistent with PJ is proposed as a relevant source of practice exploration for these forensic behavioral professionals. This instruction would focus on PJ’s core practices (i.e., commonsense justice, therapeutic jurisprudence, and restorative justice) and their corresponding principles. Legally trained clinicians armed with these mediation and ethics-based skills would then be more fully equipped to address civil and criminal mental health law disputes.

The Law–Psychology–Justice Approach

The future direction of the law–psychology–justice model includes the expansion of integrative coursework and continuing education, changes in academic inquiry and research methodology, experimental field training and practicum placements, and novel programming in human service and social welfare policy and practice. These collective reforms would be derived from the ethics-based philosophy of PJ. Thus, probing the intersections and syntheses of commonsense justice, therapeutic jurisprudence, and restorative justice is foundational for maximizing each undertaking’s potential.

Curricular and related educational offerings in forensic psychology (e.g., Law and Human Behavior, Humanitarian Ethics, Juvenile and Family Law, Criminal Psychology) await development. In each course, concerns for rediagnosing madness, re-advancing citizenship, and revisiting social justice would inform the pedagogy. A research enterprise that studies the forces of captivity and risk management also is needed. The investigatory focus would examine where and how habits of character (i.e., virtues) inform all facets of behavioral forensic science decision making. Where human flourishing for one and about all is limited or denied, research strategies for overcoming this harm by way of assessment instruments, psychotherapeutic interventions, and institutional programming would be established. The relevance of these scientific findings and the normative critique on which they are based would extend to community-based treatments. The praxis of these new initiatives would emphasize the mutuality of human agency – social structure insight and change. This is solution-focused mindfulness, ultimately benefiting the kept and their keepers, their managers, and their watchers. The solution would assess the conditions of control (i.e., the interdependent intensities that coproduce human agency – social structural injury or harm). The constitutive forces of this woundedness render our images, texts, embodied practices, and cultural representations about offenders and victims, violence and victimization, treatment and recovery, health and restoration, etc., incomplete or less than what they could be or could become. Community-based praxis in the law–psychology–justice model endeavors to overcome this harm through the exercise of dynamic and transformative character-building habits.

Forensic Phonetics

H Hollien, University of Florida, Gainesville, FL, USA

© 2013 Elsevier Ltd. All rights reserved.

Introduction

Forensic phonetics is one of a group of three related disciplines within the forensic sciences. All are structured to meet the relevant needs of criminal justice, judicial, and intelligence agencies. Forensic communication includes:

1. Forensic phonetics, a specialty in which knowledge about the human communicative processes is applied to the needs cited above by application of specialized techniques. It includes speaker identification, decoding spoken messages, analysis of emotions in voice, authentication of recordings, and related functions.
2. Forensic linguistics that targets language (written or spoken) which is analyzed to determine authorship, intent of the individual, deception, and so on.
3. Forensic psychoacoustics that relates to human hearing or audition. In this case, the analyses involve heard signals and their effect (acoustic, perceptual, neural) on individuals and their behaviors.

Definition

Forensic phonetics consists of two major elements. One involves the electroacoustical analysis of those speech signals which have been transmitted and stored; the other, analyses of the communicative acts themselves. Specifically, the first addresses how to properly transmit and store spoken exchanges, the authentication of recordings, the enhancement of speech intelligibility, speech decoding (including accuracy of transcripts), and the like. The second area involves issues such as recognition of speakers from voice analysis, identification of the health, emotional, or psychological states of the talker and the analysis of speech for evidence of deception. A number of secondary areas are not included in the lists above. Forensic phoneticians interact with forensic linguists (for language analysis), forensic psychoacousticians (for auditor-perceptual issues), and audio engineers (for nonhuman signal analysis). These have not been included because they will not be discussed in this brief review. What is featured here will be (1) the integrity of captured utterances (and related), (2) the accuracy/completeness of messages, (3) the identification of the human producing the utterances, and (4) the various psychological states (including stress and deception) being experienced.

Signal Analysis

The *analyses* of electroacoustical transmissions or stored speech signals are carried out for a number of law enforcement and judicial purposes. The major areas follow.

Authenticating Recordings

As is well known, certain specialists exist who can make any individual appear to say almost anything the operator

wishes – that is, if a quantity of the target person's recorded speech, plus good equipment and the appropriate technical knowledge, is available. This possibility can be serious (re: investigations, trials) when someone involved claims that a particular recording was 'doctored' and, hence, some of the information it contains is false. Thus, before a recording can be considered 'authentic,' it must be shown NOT to have been fraudulently constructed. Its integrity must be examined: (1) if its authenticity is challenged, (2) to defend it or (3) to determine 'what happened.' To be valid, it must include the complete set of all events that occurred and nothing must have been added, changed, or deleted during the recording period or subsequently. It also must be understood that no matter how pristine its source (individual or agency), if the recording is to be properly authenticated, it must be analyzed thoroughly and ethically. To do this, the forensic phonetician must apply knowledge about the intricacies of the speech act, technical information about the modern processing/storing of speech and appropriate electronic/computer analysis technologies.

A number of different systems store speech included are analog, digital, and video recorders (specialized tests must be added for the latter). Evaluations include both physical examinations and signal assessment. Procedures commence with a log being established, high-quality copies made, and the recording listened to for familiarization purposes. Chain-of-custody and identification marks from all sources should be checked.

Physical examination

The first procedure is to determine if signal duration is correct. Any external timing information available should be employed as should the length/time of recording tape (if that medium used). Timing signals also are useful; they can be found on many types of recordings. Announcements of time, images of clocks (on video) and related, should be checked. The second examination is focused on housing – boxes, cassettes, reels – which is examined for modifications, damage, etc. If tapes are used, they must be examined for splices; digital systems for interrupts. If any are found, it must be assumed that editing has taken place and the entire area carefully examined. The unit upon which the recording purportedly was made must be examined and tested. The procedures here involve making a series of test recordings under conditions of quiet, noise, and speech, and repeating them while serially operating all system switches. If the recording is an original, the electronic signatures found on it will be the same as those produced by that unit. Also obtained must be information of stop-and-start activity, over-recordings, and so on. Finally, other methods may be employed, for example 'tracks' made by the recorder drive mechanism, the magnetic recording patterns or codes. These processes can be complex and they vary from medium to medium.

Laboratory examination

High-quality copies of the 'originals' must be made and subjected to laboratory tests. First, the recording is listened to

in detail and all questionable events logged; that process is repeated. Questionable events include clicks, pulses, thumps, clangs, rings, crackles, etc. They also may involve loss of signal, abrupt shifts in ambient noise or amplitude, inappropriate noises as well as breaks in (or difficulty with) context, word boundaries or coarticulation. Analysis protocol in this last area is of significance – especially since it transcends operation of the several types of recorders. In any case, all questionable events must be identified and recorded. Next, it is necessary to systematically identify and/or explain the causes of these (observed) events. Some will be innocuous; examples: a telephone disconnect, a door closing, a change in microphone position, operation of interface equipment, etc. On the other hand, any of them could signal an intent to modify.

The procedures by which the questionable events are evaluated will vary; time–amplitude and/or spectral analyses are examples (Figure 1). Here an abrupt change in a waterfall-type spectrum signals that the recording probably has had a section removed. In any case, every questionable event must be identified and explained. This process is difficult and, while most of the suspicious events will be found to be ‘innocent,’ it is important not to miss any evidence of manipulation.

Finally, it must be remembered that even if it is demonstrated that the recording has been edited, the reason for modification cannot be specified. It could have been either accidental or intentional; the examiner has no way of knowing which is the case.

Speech Enhancement

An important area within forensic phonetics is that of intelligibility enhancement of recorded speech (e.g., captured during surveillance) and the development of speech decoding techniques. The importance to law enforcement and intelligence agencies results from their need for accurate logs, transcripts,

and related. Unfortunately, recordings made for these purposes are often of poor quality with the primary sources of such degradation being noise and distortion. In turn, these result from poor quality equipment, poorly trained operators, and/or hostile environments. Specifically, speech is degraded by: (1) reduction of frequency bandwidth, (2) addition of noise (of any type), (3) reduction of the energy level, (4) spectral or harmonic distortion, (5) inadequate transmission links or coupling, (6) inadequate pickup transducers (microphones, ‘bugs,’ telephones), (7) operator error, and so on. Masked or degraded speech also can result from environmental factors; they include external ‘hum,’ the wind, vehicle movement, fans/blowers, clothing friction, other talkers, music, or ‘forensic’ noise. Whatever the causes, all events must be analyzed and compensatory actions taken. The remedies here include several types of electronic filtering, noise elimination programs, restructuring the speech signal, and decoding.

The first of the cited remedies involves filtering by analog or digital equipment and/or computer software. If there is a substantial amount of noise at either (or both) the extreme lows and highs, speech may be enhanced by band-pass filters (frequency range 300–3500 Hz). Second, if spectrum analyses show that a relatively narrow band of high energy exists at a specific frequency, a notch filter may be employed. Third, comb filters (especially programmable ones) can provide an assist when noise exists *within* the frequency range for speech. They can be used to continuously modify the spectrum of a signal by selectively attenuating relatively narrow frequency bands throughout its range. Of course, filtering here must be carefully applied so as not to remove necessary speech elements along with the unwanted sounds. Finally, these procedures are best carried out with systems that have been expressly developed to compensate for multiple noise problems.

Since binaural listening also is helpful, the equipment should be organized to permit stereo listening by the operator.

Figure 1 A continuous frequency amplitude spectra (i.e., a waterfall plot) of a rerecorded splice. Note the very abrupt break about halfway in its duration.

Further, use of variable-speed recorders is recommended. One type involves a manual increase or decrease of recorder speed; it compensates for distortion resulting from the original recorder speed being varied. A second type has compensatory circuits which allow the perceived speech to appear undistorted. Finally, other useful techniques include filling in short dropouts with thermal noise, using linear predictive coefficients, deconvolution, bandwidth compression, etc.

Speech Decoding

Difficulty in providing an accurate transcript occurs when the content of some or all of the recorded utterances remains obscured. Forensic phoneticians are specialists who can deal effectively with this problem plus (1) voice disguise, (2) dialects (and/or foreign languages), (3) very fast speech, (4) multiple speakers, and (5) the effects of stress, fatigue, intoxication, drugs, health states, etc.

To be successful, a decoder should use the best equipment possible, repeatedly monitor the entire recording, apply any intelligibility enhancing techniques available, and then initiate the process by focusing on the relatively easy-to-decode sections. As is well known, speech/language is quite redundant, words have an effect upon one another (coarticulation), context aids intelligibility, and determination of one word in a multiword series (context analysis) often can aid in the correct identification of the other words. Decoding also can be aided by the use of graphic displays of the speech signal. Particularly useful here are sound spectrograms of the time–frequency–amplitude class. Displays of this type can be used to estimate (1) the vowel used (from its formants), (2) the consonant used from among several classes, (3) the consonant spoken by comparison of its energy distributions to identifiable productions, and so on. Other techniques also are available.

Basic knowledge about, and skills in applying, many of the phonetic and linguistic realities of language and speech are also quite helpful. For example, a basic understanding of the nature and structure of vowels, consonants, and other speech elements is necessary. So too is a good understanding of word boundaries, word structure, dialect, linguistic stress patterns, and paralinguistic elements of speech (fundamental frequency, vocal intensity, phoneme/word duration, and so on). Especially useful is a thorough understanding of coarticulation and its effects on other words and phrases. In short, speech/language systems can be differently employed for decoding purposes.

The reporting structure, or decoding mechanics, must be as highly organized as the decoding process itself. That is, it is not appropriate to simply write down the words and phrases heard (and verified), it is also necessary to explain what went on during the recording period and what is missing. Codes are useful here, but they must be used consistently and systematically. If sections are found where the speech is audible but not intelligible, more information must be provided than simply the word 'inaudible.' Note the following: '10 s unintelligible speech by talker A' or '6–8 words of inaudible response.' Another requisite is to include all occurring events; that is, 'Talker C: "Help me" (footsteps, door closing, two gunshots, loud thump).' Once the decoding basics have been completed

and confusions resolved, the text can be structured in final form and carefully reevaluated for errors.

Speaker Identification

Speaker identification should not be confused with speaker verification. The second of these two processes (verification) results when a known and cooperative person *wants* to be recognized from his or her speech. Thus, they will provide speech samples in order to permit construction of 'reference sets.' The target individual is later verified when a new speech sample is compared to these referents and the decision made: correct speaker or imposter? While speaker verification techniques are useful (in industry, government, military), they are only occasionally employed in law enforcement. Ironically, however, since speaker *identification* is a far more difficult task, any technique that will work for identification purposes will work even better for verification.

Speaker identification is a process where attempts are made to identify an individual from his or her speech when that person's identity is *not* known and when anyone within a relatively large, open-ended population could have been the talker. This problem, while of considerable importance, is a difficult one to solve. First, in the forensic (or intelligence) situation, all sorts of system and speaker distortions are present; samples are never contemporary, speakers usually are uncooperative; equipment often is poor, and decision criteria are difficult to establish. Moreover, the 'sets' of talkers always are open-ended (i.e., one is never sure that the criminal is among the suspects).

Considerable work has been carried out on this issue; it has focused on three areas: (1) aural–perceptual approaches, (2) 'voiceprints,' and (3) machine–computer approaches. Only the first and third of these will be reviewed as 'voiceprints' have been shown to be totally inadequate and, thus, pretty much discarded. Hence, it would not be appropriate, in this short review, to describe an invalid technique.

Aural–perceptual approaches take two forms; the first of these involves ear witnesses. That is, some courts permit a lay witness to testify but only if they are able to satisfy the jurist that they 'really know' what the speaker sounds like. In the second case, qualified experts are permitted to render opinions. Here, a sample of the unknown talker's speech (evidence recording) must be available – so too must an exemplar of the suspect. An examination is carried out and it is determined if the two recordings contain, or do not contain, the voice of but one person.

Earwitness Identification

Basically, an earwitness lineup is defined as a process where a person who has heard, but not seen, a perpetrator attempts to pick his or her voice from a group of voices. It ordinarily is conducted by the police or agents. They have the witness listen to the suspect's exemplar embedded in a group of 3–6 samples of other people. Good speaker identification accuracy can be possible if (1) the listener remembers the talkers speech patterns, (2) reasonably good samples are available, and

(3) negative emotions do not interfere. As with eyewitness identifications, the witness is required to observe the 'group' and choose who the perpetrator is. However, this approach has come under fire. Much better protocol for these auditory lineups have been developed by the present author (see Hollien).

Aural-Perceptual Approaches

A substantial amount of research has been carried out in support of strategies employed by individuals (i.e., forensic phoneticians) who conduct speaker-specific aural-perceptual identifications of talkers. In this regard, many specialists argue that aural-perceptual approaches by trained humans are the most accurate of all available methods. However, it is important to use listeners (1) with natural talent, (2) who employ 'natural' speaking characteristics, and (most important) (3) are phoneticians who are cross-trained in forensics. In any event, it is now well established that they are able to carry out valid speaker identifications. Indeed, a number of them have independently demonstrated valid analysis techniques and excellent identification rates. However, their approaches vary. Many attempt to determine a talker's identity by assessing speech segmentals (i.e., speech sounds). Such procedures are usually successful if the practitioner establishes a robust set of criteria to follow and is well trained/experienced. But, an even more powerful technique is one that is rigorously structured but uses suprasegmental assessments of voice – that is, prosody, frequency patterns, vocal intensity, quality, and so on – supplemented by the segmental analysis.

The method cited here (see Figure 2) involves obtaining samples of the unknown (evidence recording) and known (exemplar) speaker(s) and placing them in pairs on a high-quality recording. The pairs are played repeatedly and comparisons are made of *one* speech parameter at a time. Each characteristic (e.g., pitch patterns) is evaluated continually until a judgment is made. The next parameter is then assessed and the process replicated until all possible comparisons have been completed. Subsequently, decisions are made and a confidence level generated. The entire process is repeated independently and a number of times.

If the overall range of scores resulting from this procedure fall between 0 and 3, a match *cannot* be made and the samples probably were produced by two different people. If these scores fall between 7 and 10, a reasonably robust match is established. Scores between 4 and 6 are generally neutral. Incidentally, if foils are used and the mean scores polarize, the resulting confidence level is enhanced. Excellent data now are available about phoneticians' abilities to make good suprasegmental analyses of aural-perceptual speaker identifications. That is, if the task is highly structured and the auditors are well-trained professionals who demonstrate good competency.

Machine-Computer Approaches

The speaker recognition issue changes radically when efforts are made to apply modern technology to the problem. Indeed, while it would appear that solutions are now easily possible, such is not the case. Worse yet, most of the research effort here has gone into studying speaker verification not identification.

It now would appear necessary to address the more important identification problem. Figure 3 illustrates a good way to develop and test a machine-based system. Here, a group of vectors or relationships are chosen and then researched. The process proceeds step by step to assessments of multiple test vectors, distorted speech conditions, field studies, etc. While no (single) vector may be found which *alone* is robust enough to permit efficient identifications under any and all conditions, a multiple vector approach can be effective. One of the successful efforts here is the SAUSI program being carried out at the University of Florida.

Their initial step was to identify and evaluate a number of parameters. It was discovered early on that traditional approaches to signal processing were lacking, hence, *speech* features were adopted – a decision supported by early experiments, the aural-perceptual research literature and the realization that humans use them extensively. Those selected were speaking fundamental frequency (SFF), voice quality (LTS), vowel formants (VFT) and temporal patterning or prosody (TED). A full description can be found in Hollien. Since no single SAUSI vector seemed to provide appropriately high levels of correct identification for all types of speech encountered, they were normalized, combined into a single unit and organized as a two-dimensional continuum or profile. This procedure also addressed the forensic limitations imposed on the identification task (i.e., one referent; one test sample within a field of competing samples) within a research design employing forced matches (or nonmatches) of a large population. After the profile is generated, the process is replicated several times. The final continuum usually consists of the data from 3 to 5 rotations and includes a summation of all vectors. Hence, any decision made about identity is based on several million individual comparisons (factors, parameters, vectors, rotations).

A practical illustration of how this procedure works may be found in Figure 4. The evaluation here (a real-life case) involved unknown (U) and known (K) talkers plus a number of foils (F). As can be seen, the unknown speaker (U) was found to place close to himself (a test of validity); so did the known speaker (K) with the foils occurring in other parts of the continuum; hence, a match could be made. Case outcome provided (nonscientific) support for this judgment.

A summary of several SAUSI experiments can be found in Figure 5. The first of these (1988) involved high fidelity samples of a large number of subjects. None of the individual vectors provided 100% correct identification. The second part of that project (not shown) was designed to test the proposition that SAUSI would eliminate a known speaker if he was not also the unknown; it did so and at a correct level of 100%. The second set of experiments (1993) involved separate replications for high fidelity, noise, and telephone passband. Here, the upgrading of the vectors resulted in a marked improvement for all conditions. Next, the 1993 experiments provided correct identifications that were strikingly higher for all conditions and the correct identification level reached 100% for all summed rotations. Finally, yet newer research (2009) further supports the position that machine-based approaches of speaker identification are feasible and those vectors based on natural speech features are most robust.

Figure 2 A structured protocol for recording scores resulting from aural-perceptual speaker identification evaluations. Each parameter is rated on a continuum ranging from 0 (definitely two individuals) to 10 (production by a single person). The resulting scores are summed and converted to a percentage which, in turn, can be viewed as a confidence-level estimate.

Vocal Behaviors

A number of psychological or physiological states often can be identified by speech and voice analysis. Of these, three have been selected for brief review. Two are psychological stress and intoxication; a third – deception – will also be considered but more in the context of commercial devices.

Stress

Stress is a condition that denotes a negative psychological emotion. A reasonable definition of it is that it is a psychological state which results from a response to a perceived threat and is accompanied by the specific emotions of fear and/or anxiety. Further, it has been shown that listeners can accurately identify stress from speech samples alone. How do they do this? First, increases in pitch or SFF appear to correlate with stress increments. Second, frequency variability too can

correlate even though it is a less robust predictor. Third, vocal intensity is another acoustic parameter that correlates with psychological stress and, while data here are a little ‘mixed,’ the best evidence is that it tends to increase with stress. A fourth relationship is a temporal pattern of fewer speech bursts. Finally, an important recent finding is that speaker nonfluencies also appear to increase with stress increments. On these bases, a predictive model of the vocal correlates of stress has been developed; it may be found in [Figure 6](#). As may be seen, changes occur for all listed parameters. Nonetheless, it should be stressed that information of this type will be of greatest value when it can be contrasted with reference profiles for that person’s normal speech.

Alcohol-Speech Relationships

Almost anyone who is asked to do so probably will describe the speech of an inebriated talker as ‘slurred,’ ‘misarticulated,’

Figure 3 A structured research approach for the development of computer-based speaker identification systems.

Figure 4 An example taken from a real-life investigation. In this case, U can be seen as best match to himself (validity test) and K's sample also matches closely to (unknown's) reference sample. Since all foils are in a different part of the continuum, a match can be said to have been made.

or 'confused.' But, what are its actual correlates? Is it possible to determine a person's sobriety solely from analysis of his or her speech?

The rationale for an intoxication–speech relationship has been established. It is well known that both cognitive function and sensory–motor performance can be impaired by chemical means, so too can the speech act which results from operation of a number of high-level integrated neural systems (sensory, cognitive, motor). Hence, from these relationships and past research, it can be argued that articulation probably is degraded, speech rate may be slowed, and perception of impairment raised as intoxication increases. Degradations in morphology and/or syntax also have been reported.

An extensive program of research was conducted at the University of Florida and a number of reports have been published. Since other behavioral states – stress, fatigue, depression,

emotions, etc. – could complicate attempts to determine intoxication level from speech analysis, the investigators there structured new and innovative protocol. They were designed to induce acute alcohol intoxication under highly controlled conditions by administering doses of 80-proof liquor mixed with both a soft drink and Gatorade. Subjects drank at their own pace and breath alcohol concentration (BrAC) levels were measured at 10–15 min intervals. These approaches were efficient with nausea and discomfort sharply reduced, serial measurements permitted, and intoxication level accurately tracked. Hence, large drinker-class groups were studied with subjects participating in all procedures related to their experiment. Data were taken at 'windows' of intoxication levels including (among others) BrAC 0.00 (sober), BrAC 0.04–0.05 (mild), BrAC 0.08–0.09 (moderate), and BrAC 0.12–0.13 (severe). Subjects were carefully selected on the basis of 27 behavioral and

Figure 6 Model of the most common shifts in the voice and speech of individuals who are experiencing psychological stress. SFF, speaking fundamental frequency; NF, nonfluencies; VI, vocal intensity; SB, number of speech bursts per unit of time.

Figure 7 Perceived intoxication level contrasted to the physiologically measured levels (45-degree line with circles) from sober to severely intoxicated (BrAC 0.12–0.13). Four studies are combined for the top set (35 talkers, 85 listeners) and two for the lower (36 talkers, 52 listeners). Note the overreaction to the speech of people when mildly intoxicated and the underrating when they are seriously inebriated.

medical criteria. After training, they were required to produce four types of speech at each intoxication level: (1) oral and extemporaneous passages, (2) articulation and diadochokinetic tests. As is obvious, very careful and precise procedures were carried out for all conditions and levels. The nine experiments completed included auditory processing by listeners (drunk-sober, intoxication level, etc.), acoustic analysis of the signal, and various classification/sorting (behavioral) tests. A large base population, plus actors and binge drinkers, were studied.

A number of relationships emerged. Auditors tend to overestimate speaker impairment for individuals who are only mildly (to moderately) intoxicated and, then, underestimate involvement level of the severely intoxicated (see Figure 7). Second, it appears possible to accurately mimic rather severe levels of intoxication and, conversely, reduce the percept of

intoxication if an inebriated individual attempts to sound sober. Moreover, there appeared to be only minor gender differences and few to none for drinking level (light, moderate, heavy). Perhaps the most useable relationships can be found in Figure 8. As can be seen, they show shifts for all of the speaking characteristics measured excepting vocal intensity. Note also that, as intoxication increases, SFF (heard pitch) is raised and speech is slowed. Finally, a very high correlation exists between nonfluencies and intoxication level.

Deception

Relatively few of the experiments carried out in this area have been on basic speech-deception relationships; most have focused on assessing 'truth machines.' Consequently, this area is

Figure 8 The shifts in several speech parameters as a function of increasing intoxication. The increase in F0 and reduction in speaking rate (increased duration) are statistically significant; however, they are dwarfed by the dramatic shift in nonfluencies.

not well developed – a condition primarily due to the lack of support for basic research and, especially, because it has been dramatically overshadowed by the controversy about the voice stress/lie detecting devices. At present, many such devices exist (i.e., VSA, PSE, computer voice stress analyzer (CVSA), layered voice analyzer (LVA)). In all cases, their manufacturers claim that they can be used to detect stress and lying by their use in analyzing a subject's voice. Of course, if these devices actually were able to detect when a person was lying, they would be of inestimable value to legal, law enforcement, intelligence, and related agencies. For example, consider what would happen if it were possible to determine the beliefs and intent of politicians simply from hearing them speak. Moreover, there would be no need for trials by jury as the guilt or innocence of anyone accused of a crime could be determined by simply asking them: 'Did you do it?' But, to qualify as a 'lie response' the observed behavior would have to be validly measurable and every person would have to exhibit it whenever he or she lied. But, upon what criteria or theories are the cited 'analyzers' based? Unfortunately, it is almost impossible to answer this question as their maker's explanations are quite vague. One is that they access the microtremors in the laryngeal muscles. Such microtremors do exist in the body's long muscles but data confirm that they do not exist in the larynx and, even if they did, that they could not affect the actions of the complexly interacting respiratory, laryngeal, and vocal tract motor units. Other manufacturers (i.e., LVA) claim that they use an individual's thoughts 'or intent' as their foundation – and nearly all of them appear to rely on the presence of stress. But, is stress somehow equivalent to lying in the first place? A myriad of such questions can be asked but, at present, the manufacturers offer no explanations or valid support for their claims. Furthermore, of the scores of

studies that have been carried out by independent investigators, nearly all refute the claims of validity.

A large research project consisting of both field and laboratory experiments was carried out at the University of Florida. It focused on the National Institute of Truth Verification's (NITV) CVSA and Nemesysco's LVA.

In order to be fair, the experiments were designed to compensate for prior criticism of research on products of this type. They employed speech samples recorded by subjects who *systematically* varied intensely deceptive and stressed speech. To do so, they had to hold very strong views about an issue and were required to make sharply derogatory statements about them while believing that they would be observed doing so by colleagues and friends. The stress levels (further enhanced by the addition of electric shock) were externally measured for all subjects to ensure that the deception was produced at very high levels of jeopardy. Each system was then evaluated – using a double blind protocol – by (1) a UF team trained/certified by NITV – and also LVA and (2) teams of senior CVSA personnel provided by NITV and, for LVA, a pair of their senior instructors. The results for the sets of 300 samples each were subjected to a variety of statistical analysis. All were negative with the most robust being the sensitivity measures of d' (d prime). None of the results (see Figure 9) can be seen to even approach significance (i.e., the +1.00 level). These data held for all procedures, systems, and teams. Other research, plus our field studies, confirmed these findings. In short, it is clear that neither the CVSA nor the LVA devices were able to detect deception; indeed, both operated only at chance levels. The only approach practitioners can use here is to employ those deception vectors that have been generated from basic research.

Figure 9 Sensitivity measures (d') for two devices studied (CVSA on left and LVA on right). One assessment team (IASCP, UF) was staffed by the same two scientists; the other two teams (CVSA team; LVA team) were provided by the respective manufacturers. Note that all scores are well below the cutoff for *minimal* sensitivity, meaning that the devices performed only at chance levels.

Summary

The subspecialty of forensic phonetics is a dynamic and growing area. Some of its systems are quite well established while others need refinement. Fortunately, relevant data, procedures, and baseline materials are currently being developed by both practitioners and scientists.

Forensic Linguistics

R Perkins and T Grant, Aston University, Birmingham, UK

© 2013 Elsevier Ltd. All rights reserved.

Forensic linguistics is a branch of applied linguistics relating to the law and legal processes. The discipline subsumes a wide variety of research and casework and it is suggested by Coulthard, Grant, and Kredens that forensic linguistics is the application of linguistics to three main areas; “written legal texts, spoken legal practices, and the provision of evidence for criminal and civil investigations and courtroom disputes” (p. 529). This article follows these same approximate divisions, although these themes are not always clearly distinct from each other. Forensic phonetics will be discussed elsewhere in this encyclopedia.

Forensic linguistics is a relatively new discipline. The creation of forensic linguistics as a distinct field within applied linguistics is frequently linked to Jan Svartvik and his book, *The Evans Statements: A Case for Forensic Linguistics*. Like many early publications relating to forensic linguistics, Svartvik's book detailed casework and discussed the methods used to draw conclusions relating to authorship of the text(s). In his book, Svartvik introduced his analysis of the ‘confession’ statements that Timothy Evans gave to police. Evans was a Welshman found guilty of murdering his wife and very young daughter and was sentenced to death in 1950, but he was posthumously pardoned in 1966. Svartvik used a combination of qualitative and quantitative analyses to raise doubt about the authorship of the documents. He demonstrated that there were inconsistencies across the statements including noticeably different grammar in certain incriminating sections and suggests that these linguistic features indicate police insertions into the otherwise innocent statement.

Today forensic linguistics is a widely recognized field. The International Association of Forensic Linguists “aims to bring together those working on any aspects of language and the law” (<http://www.iafl.org/>) and works to promote research “into the practice, improvement, and ethics of expert testimony and the presentation of linguistic evidence, as well as legal interpreting and translation” and is working to create a standard for forensic linguistic experts. The key journal in this area is *The International Journal of Speech, Language and the Law* formerly titled *Forensic Linguistics*.

Written Legal Language

Much research within the field of forensic linguistics is interested in the interface between legal language (and legal professionals) and lay people. It is evident that the law is heavily dependent on language, as Gibbons states “The law is an overwhelmingly linguistic institution. Laws are coded in language and the concepts that are used to construct the law are accessible only through language” (p. 1). Language both enables and constrains the law, and legal language is often seen as difficult to understand, such that the only people who can truly comprehend the law as it is written are trained legal professionals.

The result of this is that the majority of the public struggle to access the laws which govern so much of their lives.

Only a historically short time ago, even consumer texts were written in dense *legalese*:

Whereas the Insured named in the schedule hereto has by a signed proposal and declaration which proposal and declaration that Insured has agreed shall be the basis of this contract and be held as incorporated herein applied to the Company for insurance against the contingencies hereinafter specified

The above paragraph taken from a 1963 Household Insurance document from the United Kingdom contains several features which have been identified as typical of legal writing: there is no punctuation; the use of self-referential terms and archaic terms (such as ‘herein’) which is often associated with legal language; and the use of duplicate terms, so-called, doublets or binomial expressions such as the repeated use of ‘proposal and declaration.’ Although the two terms used here both have their roots in French, it is common in British legal texts that within such doublets one finds one term with a Norman French etymology and one from Old English or Latin (p. 43). The best-known example of this would be the binomial: *will and testament* the term *will* having originated in Old English and the term *testament* having its etymological roots in Latin and French.

Although the insurance text is from 1963 such features can still be found in contemporary consumer documents, in written criminal codes, and in lay legal texts such as restraining orders or (in the American system) judges written instructions to juries. The occurrence of legalese has provoked a counter movement of plain language campaigns. Such attempted reforms, however, have thus far got little traction. Notable exceptions include Gibbons involvement in the redrafting of the New South Wales police caution and Tiersma's work on the California pattern jury instructions.

Although the tripartite division of forensic linguistics into the study of written legal texts, spoken interaction, and investigative work is well accepted, linguists generally recognize that the distinction between spoken and written texts is somewhat unclear and arbitrary. The police caution is a good example of a written legal text which has to be performed as a spoken interaction. In the United Kingdom, the current police caution currently reads thus:

You do not have to say anything. But it may harm your defence if you do not mention when questioned something which you later rely on in court. Anything you do say may be given in evidence. (Police and Criminal Evidence Act, 1984, code C, p. 34)

The caution is a statement given by police officers to inform detainees of their rights once they have been arrested and again before any interviews. Police officers are given the freedom to deviate from this exact wording and are encouraged to ensure

that the caution is understood by those it is being read to. PACE (the Police and Criminal Evidence Act) states that "Minor deviations from the words of any caution given in accordance with this Code do not constitute a breach of this Code, provided the sense of the relevant caution is preserved" (p. 35). Linguists have expressed considerable concern about the comprehensibility and effectiveness of such cautions. Cotterill was able to show that few people were able to describe their legal rights having been cautioned and although Rock describes considerable work done by the police at the beginning of interviews in the communication of rights she also agrees that the delivery of the caution has doubtful communicative value. Solan and Tiersma note that even after the successful delivery of the US Miranda rights, suspects find it very difficult to assert the rights apparently delivered to them through the interaction. Linguists have had little success in their attempts to reform the wording or practice of cautioning and identify one principle difficulty as being that the caution is structured as a written text but needs to be performed through spoken language and this issue was not appreciated by the drafters.

Spoken Legal Language

Interactions within the legal system which are more clearly spoken are also subject to research by forensic linguists and these include police investigative interviews and also courtroom interactions. The field of research into investigative interviewing has been dominated by psychological inputs, mainly examining how to extract maximum good detail from cooperative or noncooperative witnesses and suspects, as well as from those (including children or adults) with learning difficulties. There is, however, an increasing contribution from linguists (including Heydon; Aldridge and Wood; and Stokoe and Edwards) which focuses on the interactional process of an interview. One good example of such work is Haworth's concentration on how, in the UK system, the interview tape or transcript is used within the wider legal process. Her thesis is that the police officers are more aware that the interview is part of an evidential chain and this causes them to use language differently from lay witnesses and gives their contributions greater weight with the future audiences of the Court.

One area where linguists can make a considerable contribution is with those who might be considered linguistically vulnerable. The occurrence of bilingual discourse within a legal context is increasing (even when not considering translated discourse); despite this many people – including legal and linguistic professionals – consider monolingual courtroom discourse as more standard. This can provide significant problems of access for the increasing number of people who find themselves in a legal situation based in a language other than their mother tongue. Linguists (e.g., Kredens and Morris) have been examining these interactions with a view to better training interviewing police officers in management of interpreters in interviews and in assisting court officials in their courtroom roles.

Communicative difficulties result not only from issues of second language competence but also from cultural differences

between communities that speak the same language. Diana Eades, for example, highlights the cultural differences between Australian Aboriginal peoples and the dominant white culture where both groups use varieties of English in their everyday communications. One of the areas of difference which Eades points out is in the use of silence. In Standard Australian English, a long period of silence may indicate uncertainty or a lack of cooperation from a witness and this can diminish a witness's credibility. However, in Aboriginal cultures, silence can be used as a sign of respect and politeness to show that you are fully considering a question before answering it giving a long pause a more positive social effect. Such differences as this, Eades argues, can lead to the Aboriginal witnesses appearing less trustworthy due to the cultural dislocation.

While the study of written legal language and spoken interaction both have significant practical implications for the delivery of justice, linguists are also involved in investigative work and the provision of evidence and it is to this we turn next.

Investigative Linguistics and Provision of Evidence

Linguists are sometimes asked to provide either expert evidence in court or expert advice to aid police investigations. From the lay perspective, the prototypical activity might be seen to be comparative authorship analysis, where a linguist compares an anonymous text to the known writings of an individual to determine whether or not they are one and the same author. Although linguists do engage in this work it is only one of the tasks undertaken.

Comparative Authorship Analysis

Comparative authorship analysis of long texts is increasingly dependent heavily on multivariate computational techniques, which can be shown to be reliable but offer little explanation as to the outcome. This validity deficit means that such techniques tend not to be depended upon by the forensic analyst and in any case such techniques often require more text than is available in forensic casework. Perhaps surprisingly considerable progress in forensic comparative authorship analysis has been made with the very short texts of SMS text messaging and other short form messages such as Twitter feeds. There have been a number of UK cases when a person is missing presumed dead, but their mobile phone has continued to send text messages. In such cases, linguists have been consulted to see if the suspect messages are consistent with the missing person, the suspect, or neither. One such example worked on by Malcolm Coulthard, concerned 19-year-old Jenny Nicholl who went missing in June 2005. Although no body was ever found, her 49-year-old lover was charged and later convicted of her murder. Part of the evidence in the case was the analysis of messages sent from her phone to her friends and family after her disappearance. There were noticeable differences in the messages sent after her disappearance and the texts known to be authored by her. Among the different features was the appearance of a preceding space before number substitution, so

where Jenny is more likely to have written 'ave2 lve,' the questioned texts actually contained; 'ave 2 lve.' Coulthard's analysis did not only describe consistent patterns of written style within an author's text, it also attempted to account for the level of intraauthor variation in writing style. Coulthard's approach focussing on within author consistencies of style and between-author distinctiveness has been recently shown to be amenable to statistical analysis to support the decision making of the forensic analyst.

Sociolinguistic Profiling

Sociolinguistic profiling has evolved directly from the academic field of sociolinguistics and particularly makes use of the concept that our linguistic output is influenced by a number of social factors; including age, gender, and educational status. Sociolinguistic profiling aims to determine information about an anonymous author, or the origins of a text. The linguist does not make psychological observations about the intentions of the author or the seriousness of any threat but can sometimes describe the social origins of an individual. A good example of this process is described by Leonard. In this case, a handwritten ransom note was found on the doorstep of a kidnapped child's home:

Do you ever want to see your precious little girl again? Put \$10 000 cash in a diaper bag. Put it in the green trash kan on the devil strip at corner 18th and Carlson.
Don't bring anybody along.
No kops!! Come alone! I'll be watching you all the time. Anyone with you, deal is off and dautter is dead!!!

Linguist, Roger Shuy, was consulted by police to see if he could aid in narrowing down the suspects. His description of the suspect was remarkably precise; he was able to suggest that the author was likely to be an educated man from the small town of Akron, Ohio. This profile matched one of the police suspects, who confessed after being arrested. The education level was inferred from the pattern of misspellings in the note; these included both misspellings of simple words including: *kan* (can), *kops* (cops), and *dautter* (daughter), and the correct spelling of more complex words (e.g., *precious*). In addition to this, the grammar is well controlled and consistent with a higher level of education. This indicated to Shuy that the author was trying to disguise their writing in order to appear less educated. The key geographical element, however, was the use of the dialect item *devil strip*. Using linguistic reference works, Shuy was able to say that this term, which refers to the strip of grass, which separates the pavement (or sidewalk) and the road, is only used very locally in Akron, Ohio, and this indicated that the culprit was likely to be a native of Akron or have spent considerable time there.

Conclusions about the social background of an individual are unlikely to ever be certain enough to provide evidence against an individual in the courtroom but, as Shuy's case exemplifies, such techniques can be used investigatively to good effect.

Interactional Meaning

In addition to the above profiling case, Shuy came to prominence in part for his analysis of covert tapes used by police to

prosecute what Shuy calls 'language crimes.' Language crimes are crimes which are inherently linguistic in their nature and include threatening, extorting, bribing, etc. In examining such cases, Shuy shows again and again that covertly recorded conversations involving an undercover agent can make for poor forensic evidence of what was said and what was meant. He demonstrates how the imbalance in knowledge between the protagonists warps such conversations leading to prosecutions on the basis of linguistically questionable evidence. In one such case, an undercover recording suggests that a lawyer was willing to steal files crucial to a case in which he was involved. Shuy, however, shows how an alternative, innocent, understanding of the conversation is possible, and that the incriminating interpretation depended on an undercover police officer using camouflaged meanings, ambiguous terms, and conversational misdirection.

Determining Meaning

As well as the determination of interactional meaning linguists can also provide evidence as to the meaning of slang terms. Coulthard, Grant, and Kredens report Grant's appearance in a conspiracy to murder case. In this case, the conspiracy took place over Internet relay chat and the protagonists spoke a variety of East London slang which draws heavily on Jamaican English. One key phrase in the IRC chat transcript was "I'll get da fiend to duppy her den." In this instance, Grant was able to explain to the Court the origin and the meaning of the verb 'to duppy' (which can be traced back to Jamaican English and its approximate meaning of *ghost*) and that it did indeed indicate a threat against the victim.

Trademark Disputes and Copyright Infringement

Linguists are not only involved in criminal investigations but also contribute to civil work. This work can include authorship analysis and other tasks and also a few tasks which are exclusively civil. The most prominent of these are in the areas of trademark dispute and copyright infringement (including accusations of plagiarism). Another area in which linguists have testified as expert witnesses in court is in trademark disputes. Ronald Butters, who has regularly testified in trademark cases, split the jobs of linguists in the field of trademarks into three main areas "(1) likelihood of confusion [...] (2) categorization of the strength of a mark [...] and (3) propriety of a mark," (p. 231). Most recently, two leading linguists Robert Leonard and Ronald Butters made the news after being hired by Apple and Microsoft, respectively, regarding a dispute about the "App Store" trademark. Linguists are often consulted in such cases to investigate how a mark is understood by the general public. For example, some trademarks have become so popular and widely used, that they have become generic terms for that type of item, as opposed to relating solely to one company's products and in such a situation the trademark can be said to suffer trademark death and so become unprotected. Examples of this include; Hoover, Xerox, and Band-aid. Linguists have also testified over the similarity of terms. The case of *McDonalds v. Quality Inns* involved a dispute over the prefix *Mc-*. Quality Inns intended to open a chain of hotels called *McSleep*; however, McDonalds posited that the

use of the *Mc-* prefix gave the false impression that they were part of the McDonalds franchise. Despite the frequency with which the prefix *Mc-* is found in surnames, the case was eventually decided in favor of McDonalds and a new name had to be found for the McSleep hotels.

Conclusions and Future

Forensic linguistics as a field is very much still growing and evolving. If viewed as the application of linguistic analysis to forensic texts and contexts it is likely that the need for linguistics in a forensic context will only grow. Technological advances create potential for increasing perceived and actual anonymity, while computer forensics and other disciplines have considerable contribution to make, so too do forensic linguists.

As language itself (and the methods we use to communicate) are constantly evolving, so the field of forensic linguistics will also change and grow. Social media such as Twitter, Facebook, and Blackberry Messenger (BBM) are becoming more embroiled in forensic cases and hence there is also an increase in research examining the language of these settings and the implications for forensic linguistics. It is impossible to accurately predict the future direction of forensic linguistics, and it is likely that the field will continue to expand in many varied directions. There is a strong movement towards creating guidelines and possible accreditation for forensic linguistic experts, which will aid the field in becoming more widely recognized and utilized to its full potential.

Glossary

Appellate (appeal) The process of seeking a judicial review of a court decision by a court of higher authority or a judicial decision related thereto.

Cause of death Determination of the mode and manner of a person's death by a coroner (or a medical examiner).

Defendants Those who defend a lawsuit against them. In a criminal case, those who seek acquittal.

Equivocal death A disputed or undetermined death.

Forensic ethics Ethics especially related to judicial or semijudicial proceedings.

Manner of death Answers the 'why' in the mode of death (e.g., Why did a person fall from a great height? Did he or

she intend self-harm? Was it an accident? Was he or she pushed?).

Mode of death What made the person die (e.g., water in the lungs, a fall from a great height).

Plaintiffs Those who initiate the lawsuit.

Psychological autopsy Tools and methodologies to investigate an equivocal or undetermined death. Also used in suicide research.

Standard of care The standard to which professionals are held, by law and ethics, to conduct their professional conduct. Acting beneath that standard of care carries ethical or legal sanctions and sometimes both.

Introduction: Definitions and Usage

The goal of the psychological autopsy is to reveal the thoughts and attitudes of the deceased prior to his or her death. It is a tool and a method of analysis that uses the deceased's past records and behavior as well as current interviews with those around them. This study seeks to discern the deceased's state of mind prior to death. Psychological autopsies are used for both research and forensic purposes. In research, psychological autopsies are used to investigate the nature, patterns, and causes of suicides. In forensic investigations, psychological autopsies are used to investigate what are most often called 'equivocal deaths.' These are disputed deaths, where the intention or will of the deceased cannot be determined, such as between an accident, a suicide, and a homicide.

A psychological autopsy is a methodology and instrument used to help determine the *manner* of death as opposed to the *mode* of death. The *mode* of death is what a coroner can determine. This distinction is illustrated in a case before law where a woman was found unconscious and face-down in an empty bathtub. Medical personnel tried to revive her, but she later died in the hospital. A physical autopsy revealed consumption of antidepressants, including approximately 20 temazepam tablets. The medical examiner ruled that she drowned because she was incapacitated from that drug and that it were not taken accidentally. However, the physical autopsy could not determine whether her death was a suicide or a homicide. The psychological autopsy for the state, rendered by a clinical psychologist, suicidologist, and the Executive Director of the American Association of Suicidology, figured prominently into the criminal trial and her husband was indicted for first-degree murder. Experts conducting a psychological autopsy issue findings based upon research of the deceased and relate them to the specific issues at trial.

Today, psychological autopsies are used, in one form or another, around the world. They employ a range of studies

adapted and adopted to fit the needs of the study, the available evidence, and the demographics and cultures in which they work. Therefore, psychological autopsies allow for a variety of disciplines and expertise, with sensitivity to the bereaved and to the cultures from which they come.

Validity and Reliability of Psychological Autopsies

Due to the widely disparate nature, purposes, and disciplines of the researchers and the environments in which the autopsies will be used, the validity and reliability of psychological autopsies have been unclear, even controversial. Researchers have noted that criterion validity is nearly impossible because if the 'truth' about the deceased's intention could be known for certain, there would be no need for a psychological autopsy in the first place. In 1993, researchers conducted a systematic analysis of the Equivocal Death Analysis (EDA) protocol used to investigate lethal explosion aboard the battleship U.S.S. Iowa in 1989. A panel of experts independently reviewing the EDA reached consensus only for broad categories.

More recently, the medical model of psychological autopsies has been criticized through studies of suicides of UK young men. The studies that the sample of narratives from the parents of victims of suicide or open-verdict deaths favored moral categories over the medical ones often favored by psychological autopsies. Additionally, the reliability of psychological autopsies has been studied cross-culturally. Researchers applied a psychological autopsy, emphasizing cultural and social factors, to 66 suicide victims and 66 living controls. They found validity in applying the Western psychological autopsy approach to their Chinese sample. Significant strides have been made in assessing the reliability of psychological autopsies as valid tools for both scientific research and forensic investigations.

Legal Requirements of Psychological Autopsy Testimony

Beyond the scientific demands of pure research, psychological autopsies must also adhere to legal standards when they serve forensic functions. Psychological autopsies often become a court, a coroner's, or an insurance record. Legal requirements and certainly the professional requirements of social science demand both valid and reliable research. In US law, the Federal Rule of Evidence §702 requires that judges determine whether or not the research methodology conforms to appropriate scientific rigor. That standard is neither rigid nor infinitely flexible. It requires that trial courts avoid unproven theories and methodologies. A Louisiana appellate court affirmed the admittance of a medical doctor who performed a psychological autopsy. The decedent's wife unsuccessfully challenged the will on grounds of incapacity arguing the doctor's testimony, which was based upon the medical records, the executed wills, and the various parties, did not meet the legal standard for expert testimony. The appeals court ruled that the expert and his methodology met the §702 standard.

In another challenge to an expert's psychological autopsy testimony, a US federal district court in Georgia allowed a medical doctor to testify even though he was not qualified in the practice of many specialties at issue in a case alleging medication-caused suicide. The physician was not a suicidologist, psychopharmacologist, epidemiologist, or an expert in US drug regulation or testing. He was a board-certified psychiatrist with over 40 years of experience and had 'significant' (the court's word) training and education in suicide research. The court ruled that an expert need not be certified or admitted to the specific field under consideration.

The Methodologies

Determining the manner of death when the deceased is unavailable for contemporaneous interview and testing requires different investigative tools and skills. In equivocal deaths, this challenge is further complicated by bereavement issues, incomplete memories of interviewees, reluctance to speak about the dead, and legal complications such as insurance issues as well as the lack of essential facts without the likelihood of ever retrieving them.

Flexible and adaptive techniques toward that purpose have been used for over 50 years. These protocols examine the life-style, medical, social, and emotional histories, character evidence and traits, and anything else that bears upon the decedent's intentions related to his or her death. Such a study is inevitably broad, interdisciplinary in approach, and must be unbiased. Shneidman, a pioneer of an early and still-used protocol of the psychological autopsy, helpfully distinguishes the psychological autopsy from a physical autopsy (such as what a coroner might produce), a forensic investigation (to discover the perpetrator), and statistical and demographic reports (to study who is at risk for suicidal behavior and ways to militate against him or her). It is sometimes tempting to blur one study with another.

The methodologies for conducting a psychological autopsy allow room for adaptation to circumstance. An early, if not the first, published methodology in the modern era was instituted

by Shneidman in 1976 and another was done by Ebert in 1987. Both these important contributions investigate a wide range of medical, social, psychological, emotional, and behavioral documentary evidences (including, suicide notes and coroner's report) about the deceased.

The Queen's Bench in Alberta, Canada heard two psychological autopsies in a case where a teenage man died from carbon monoxide poisoning. His family sued the school board for negligence, alleging that humiliation, stress, and embarrassment in an incident at school caused his death. The defendant's expert, a psychiatrist, testified that the young man was not so humiliated or stressed as to commit suicide. The plaintiff's expert, a clinical psychologist, testified that the stress and embarrassment over the incident may have contributed to his death. Importantly, neither of the experts believed that the cause of death was a suicide, as determined by the medical examiner.

Both experts interviewed almost the same players in the man's life, including teachers, parents, friends, and employer, and both experts reviewed documentary evidence including school records, police reports of the school incident and his death, and the medical examiner's report. Each concluded that the most likely theory was his death being an accident and the judge was persuaded. The crucial difference between the expert testimonies was that the plaintiff's expert concluded that it was likely that the stress of the school incident contributed to the accident and the defendant's conclusion was that such stress did not.

A study that surveyed 94 US medical examiners about the factors they used to determine a child suicide revealed that the five most used factors (in descending order) were the suicide note, history of suicidality, psychological history or diagnosis of mental illness, medical history, and presuicide behavior. A psychiatric examination of Ernest Hemingway's suicide used biographies of the writer, personal correspondence, the writer's own literature, photographs, as well as medical records. Snider, Hane, and Bergman offer a standardized, yet flexible, protocol. This protocol is included as [Appendix](#) for two reasons. First, it is specifically designed to comport with the court's scrutiny of expert testimony. Second, it is clear, cogent, and comprehensive.

Even with all its variants, researchers find psychological autopsies to be the most informative and useful method for research into suicide behavior. This well-deserved respect, as will be seen, does not immunize the psychological autopsy from critiques for its reliability and validity from both the demands of science and the scrutiny of courts.

Other Protocols for Psychological Autopsies

Some researchers have offered their own protocols, particularly with a view to create a more standardized procedure while allowing for appropriate flexibility. Given the debate on the reliability and validity of psychological autopsies, researchers have emphasized the need for a standardized protocol that meets both scientific and forensic standards within the context of an equivocal death and the issues at trial.

Many researchers use a 'semistructured' interviewing process, which leaves the interviewee time to elaborate on the questions

asked. A semistructured interview for psychological autopsy with broad characteristics such as stressors, motivation, lethality, and intent was described by Werlang and Botega. Additionally, Campayo, Alvarez, and coworkers have adapted the Standardized Polyvalent Psychiatric Interview into a new psychological autopsy tool to be used with depressed patients. They call this semistructured interview the 'Bio-Psycho-Social Autopsy.'

Ethical Elements in Psychological Autopsies

Legal scholars have recognized how experts run afoul of ethical and legal standards, including violating their licensing boards, losing their testimonial immunity, and testifying below a standard of care for expert witnesses. The 'standard of care' is the 'line' above which there is no liability or guilt and below which there is either guilt or liability. Oregon's appellate court upheld the state licensing board's disciplinary action against a member, a psychologist, for making recommendation in a child custody case where the mother was a client and the psychologist did not interview the husband. The court ruled that the board had a proper standard against a psychologist who did not disclose potential bias and presented a testimony that lacked validity and reliability. Experts must comply with the ethical standards of their respective professions when making recommendations, writing evaluations, and testifying in court.

Researchers have also tested the impact of psychological autopsy interviews on the interviewees. A research study in the UK found that interviewing two persons at the same time could yield conflicts between the interviewees when they disagree on their view of the decedent's death or life situation. The study suggested that as strong emotions, including shame and guilt, could accompany such interviews, the interviewer might offer referral to counseling resources as part of the investigative process. Additionally, the study found that boundary issues could occur between an interviewer and a counselor. Some information which was undisclosed in an interview could be revealed when issues are explored in depth during a counseling session. The study raised the ethical concerns about how counseling information is used, including informed consents offered or available for research purposes.

This study also noted the need for ongoing supervision of the interviewee. It concluded that while the interviewing process did no harm and may have been helpful to the interviewees, researchers should approach their task with empathy and caution.

In another UK study, researchers conducted a follow-up session for those interviewed in previous studies of high suicide-risk groups (young adults, farmers, and doctors). The sample group was asked to assess their reactions to the interviews on suicide risk. The study found that 96% preferred being sent a letter by the initial researchers themselves. While 22% reported being upset by the interview, a month later only one interviewee reported feeling worse than usual. In contrast, one-third of the respondents reported feeling better after the interview. While all were offered bereavement information following the initial interview, less than half accepted the offer. Among those who received the information, however, 90% reported it as being helpful. The study called for follow-up evaluations after conducting interviews on suicide risk and

practice of steps that insulate against the negative effects of the interviewing process.

However, it must be emphasized that both the above-mentioned researches indicate that interviewing others about a suicide need not in itself cause harm. In fact, the participants can derive some benefits from the interview. That benefit may flow from the manner in which the interview is conducted and the follow-up afforded to interviewees.

Appendix

Recommended Documentation/Archival Records

- Medical records
- Police records
- Legal records
- Criminal records
- School records
- Financial records
- Suicide note or other documented communication (regarding suicidal ideation or death wish)
- Military records
- Autopsy report
- Toxicology report, if available

Site of Death

- Decedent's relationship to site
- Evidence of rescuability versus precaution against rescuability
- Evidence of planning and/or rehearsal

Demographics

- Immigrant status
- Acculturation issues
- Residence relative to recent mobility
- Socioeconomic status
- Employment and financial status
- Age/gender/race
- Marital status
- Educational status
- Religion and religiosity
- Adopted versus biological family status

Recent Symptoms/Behaviors

- Appeared depressed, sad, tearful, or moody
- Displayed symptoms of depression
- Expressed symptoms of depression
- Expressed suicidal ideation or thoughts of death or dying
- Appeared to have made a change for the better
- Appeared anxious or complained recently of anxiety or panic attacks
- Appeared agitated
- Behaved in an impulsive manner
- Displayed uncontrolled rage or aggressive behavior
- Demonstrated constricted thinking or 'tunnel vision'
- Disclosed feelings of guilt or shame
- Appeared confused, disoriented, or psychotic
- Expressed feelings of hopelessness, helplessness, or worthlessness
- Mental status: Evidence of:
 - Impaired memory

Poor comprehension
 Poor judgment
 Hallucinations or delusions
 Showed an inflated sense of self or signs of magical thinking
 Engaged in excessive risk-taking behaviors

Precipitants to the Death

Had the decedent recently experienced or was the decedent anticipating any of the following?
 Significant loss or losses (relationships, job, finances, prestige, self-concept, family member, moving, anything of importance to the person)
 Significant (or perceived significant) disruption of a primary relationship
 Legal troubles or difficulties with police
 An event which was or was perceived as traumatic
 Significant life changes (negative as well as positive, e.g., marriage, birth of a child, promotion, etc.)
 The successful suicide or suicidal behavior of a family member or loved one
 The anniversary of an important death or an important other loss, or another significant anniversary
 Exposure to the suicide of another through the media or personal acquaintance
 His or her death as evidenced by recently making preparations for death (e.g., updating will, insurance policies, etc.)
 Expression of a wish to reunite with a deceased loved one or to be reborn

Psychiatric History

Prior suicidal behaviors
 Any prescribed psychotropic medications for anxiety, depression, or psychosis
 Observed adverse reactions, intolerable side effects, lack of compliance, etc.
 Hospitalization in a psychiatric setting – Where? When? Diagnosis?
 Whether a therapist or psychiatrist/pharmacologist (or other, e.g., primary care provider (PCP)) was consulted in the recent past
 Being in therapy at the time of death. If so, duration, quality of therapeutic alliance and compliance with treatment, diagnosis, etc.
 Expression of concerns about ‘going crazy’ or of losing cognitive functioning

Physical Health

Recent visit to a physician (make a note of the reason)
 Experiencing chronic pain
 Recent or past diagnosis or concerns regarding a chronic, fatal, or disabling disease
 Recent reduction in physical/functional capabilities
 Current medications. If so, compliance, recent changes in dosage or prescription.

Substance Abuse

History of alcohol or drug abuse
 Recent attempts to discontinue alcohol or drug abuse; recent increase in pattern of abuse
 Degree of alcohol or drug abuse at the time of death; evidence of binge drinking

Patterns of polysubstance abuse
 History of ‘accidental overdose.’ If so, when? What drug?

Family History

A sibling or a parent who died a nonnatural death
 Level of support or observed closeness in nuclear or extended families
 Significant physical, sexual, or emotional abuse
 Substance abuse
 Suicide
 Violent behavior
 Presence of affective disorder or other mental health disorders in the family

Firearm History

Firearm ownership
 Recently purchased or otherwise obtained a weapon. If so, for what stated purpose?
 Care for weapons; what was the characteristic pattern of cleaning guns?
 Storage pattern of weapon(s)
 Accidental discharge of firearm

Attachments/Social Supports

Ability to create and maintain close personal relationships; presence of a close confidante
 Ability to express feelings as needed (especially grief and anger) in relationships
 Recent talk about feeling unsupported, uncared for, unimportant in relationships
 Relative success in:
 Personal relationships
 Work
 Attachment to hobbies, interests, religion, etc.
 Recent changes in any relationship to the above attachments

Emotional Reactivity

History of violence toward others
 Impulsive behaviors
 Excessive rage or other uncontrolled, aggressive behavior

Lifestyle/Character

Typical coping patterns
 Perfectionism
 Self-destructive behaviors (such as self-mutilation, drinking/driving, etc.)
 Frequent crises, often those appearing self-created
 Victimization behaviors, e.g. bullied

Access to Care

History of help-seeking behavior
 Known barriers to health care (e.g., lack of insurance, no accessible caregiver)

Other Areas of Inquiry

Occupational history
 Hobbies/interests
 Gambling history
 Degree of religiosity

Glossary

Actuarial prediction Predicting the likelihood of an event on the basis of statistical calculation.

Clinical prediction Predicting the likelihood of an event on the basis of professional knowledge.

Expert witness An individual with specialist knowledge in a given field who informs the court about a given case.

Risk assessment The process of estimating (using actuarially derived parameters or professional judgment) the likelihood, or risk, of an event occurring.

Special hospitals Maximum security institutions for the treatment of mentally disordered offenders.

Introduction

Psychology and Psychiatry

What is the difference between forensic psychology and forensic psychiatry? The straightforward answer is to say that forensic psychology is practised by those who have first qualified as psychologists, then trained at postgraduate level to develop the necessary specialist competencies. Forensic psychiatrists, on the other hand, have first qualified in medicine then taken further professional training to qualify as psychiatrists with a forensic specialty. In practice, forensic psychiatrists hold statutory powers and responsibilities, such as prescription of medication and supervision of patients: these powers and responsibilities are generally not given to other professions, including psychology. Several distinctions can be made between forensic psychology and psychiatry. First, psychiatrists are trained to think in terms of abnormalities in an individual's biological and medical functioning; psychologists do not have this specific focus, but are trained to consider personality, behavior, and broader social dimensions to explain an individual's behavior. Second, psychiatrists tend to draw their professional knowledge from clinical observation and research with clinical samples; psychologists rely more heavily on systematically gathered experimental data. Third, psychiatrists lean toward assessment of individual clients through clinical interview and observation; psychologists are more likely to use psychometric and other psychological tests.

The similarities between forensic psychology and psychiatry lie in a shared concern with the broad fields of crime and antisocial behavior. However, given the variations in professional training and methods, there are some distinct contrasts in the work of the two disciplines.

Traditionally, forensic psychology has its roots in the application of psychological knowledge and expertise to gather evidence for judicial purposes. It is the case that this traditional use of the term 'forensic' is closest to the dictionary meaning of the word. For example, *The Concise Oxford Dictionary* entry for 'forensic' gives, 'Of, used in, courts of law.' However, within psychology, the meaning of the term 'forensic' has broadened considerably in recent years to encompass not just the courts, but any topic connected with crime and law. Thus, some texts on forensic psychology cover subjects such as the police, treatment of offenders, risk assessment, and theories of criminal

behavior which, adhering to the dictionary definition, are not forensic.

Ronald Blackburn, a leading British psychologist, has criticized this redefining of the term forensic to cover any psychological activity 'vaguely connected with the law.' Blackburn's case is that without a meaningful definition of the term 'forensic,' and the dictionary supplies the best understood definition, a profession that calls itself forensic psychology struggles to find an identity. Without a professional identity, we are left with the question of what are the unique skills and abilities that the forensic psychologist can offer? The root of the issue, of course, is that the term 'forensic psychology' has metamorphosed from a description of an *application* of psychology to describing a *kind* of psychology.

In keeping with the traditional sense and correct use of the term forensic, discussion of forensic psychology will be limited here to the application of psychological theory and knowledge to the courts of law.

Historical Development

Forensic Psychology

It is generally taken that forensic psychology dates from 1896 when Albert von Schrenk-Notzing appeared as an expert witness in a Munich court, offering testimony at the trial of a man accused of murdering three women. The specialist knowledge that von Schrenk-Notzing – a student of Wilhelm Wundt who in 1879 founded the first psychological laboratory at the University of Leipzig – was able to put before the court was based on experimental psychological evidence on the workings of memory. Specifically, von Schrenk-Notzing argued that the memory of the witnesses to the crime being used as evidence in court was unreliable because the witnesses had become confused between their own memories for the event and the pre-trial publicity. The application of psychological knowledge and methods to the process of law attracted some of the great figures in the history of psychology, including James Cattell and Alfred Binet, while in the early 1900s other psychologists, such as G.F. Arnold and Hugo Münsterberg, were the up-and-coming specialist forensic psychologists.

The greatest of the early luminaries was another of Wilhelm Wundt's pupils, the German psychologist Hugo Münsterberg

(1863–1916). In his book *On The Witness Stand*, published in 1908, Münsterberg argued that the developing discipline of psychology could be of benefit to the process of justice. These potential benefits, Münsterberg claimed, lay not only with the application of psychological knowledge of the workings of memory to the veracity of the eyewitness, but extended to other matters such as the working of the jury. Münsterberg made the case for the psychologist's role in the courtroom as an expert witness to inform the process of justice on matters psychological. Münsterberg's arguments drew fierce attack from some quarters of the legal profession, anxious to resist the forays of psychologists into the courtroom. Nonetheless, the spread of psychology in the courtroom continued: in France in the early 1900s, Alfred Binet worked on the issue of the reliability of eyewitness memory, and in 1921 in America, psychological testimony was used in court to argue the case that a victim's testimony was doubtful because of his/her low intellect.

After the Second World War, the profession of psychology grew in sophistication with the establishment of specialist educational and clinical psychologists. At first, these newly emerging specialisms provided psychological material for inclusion in medical court reports. However, as time passed, psychologists were permitted to submit court reports in their own right, rather than have their work subsumed into a report written by another profession. As the discipline of psychology progressed from the 1950s to the present day, so psychologists gave their attention to an increasing range of courtroom issues. Importantly, the role of the psychologists as expert witnesses developed considerably: several surveys, summarized in [Table 1](#), showed that psychologists now were to testify in court on a range of topics.

Psychologists were also cultivating a research agenda that would impact on two areas of forensic psychology: first, research that would lead to greater levels of understanding with respect to the reliability of evidence; second, research that would increase dramatically the level of psychological insight into law and its application in the courtroom.

Forensic Psychiatry

If the discipline of psychology has a short history, most often traced to its beginnings in Wundt's laboratory as noted above, quite the opposite is the case for forensic psychiatry. The medical profession, of which psychiatry is a branch and forensic psychiatry a specialty within that particular branch, has a long history. Indeed, the medical historian Roy Porter traces the evolution of medicine to the end of the last Ice Age,

around 10 000–12 000 years ago, as the organization of societies shifted from hunter–gatherer to farming in order to sustain life. Porter suggests that the transmission of pathogens from animal to human led to an explosion in diseases such as tuberculosis, smallpox, measles, and typhoid. As the population settled together in ever greater numbers, so the spread of parasites such as worms, flukes, and lice increased. Similarly, changes in diet, as agriculture became the main means of food production, brought about conditions related to low protein intake and other dietary conditions. Thus, population growth and changes in societal structure heralded the onset of epidemics such as the plague. As history unfolds, each evolutionary shift brings its benefits but also takes a toll on health. The industrial revolution brought prosperity (to some) as well as illness caused by pollution; the demands of modern-day living are associated with stress-related conditions such as hypertension and excessive use of drugs and alcohol.

As illness and disease took their toll in terms of human suffering, so people tried to find ways to heal the sick and with the advent of healing so medicine was born. The historical record shows that throughout antiquity civilizations developed their own understandings of the causes and cures of illness. The great civilizations, including Babylon, Ancient Greece, Egypt, India, and China, have all left records of their theories of illness, their medical practice, and even their surgical tools. As history unfolds, so important advances were made: we see, for example, improved understanding of human anatomy, appreciation of the complexity of disease, discovery of new drugs, and technological progress from microscopes and x-rays to brain scans and microsurgery. Thus, the treatment of physical illness has roots that reach back to the very beginnings of civilization.

It is long recognized that there are some people whose illness is of a special type: madness was as familiar to the ancient Greeks as it is to contemporary society. However, there was no special branch of medicine dedicated to relieving the suffering of the mad, whose treatment and care was left to families and communities or, if all else failed, to madhouses run by charities or religious groups. It was not until the mid-eighteenth century that psychiatry began to appear as a specialized branch of medicine. The rise in the use of asylums for the insane across much of Europe and later America heralded the involvement of the medical profession with those suffering from mental disorder. The treatment of those people held in asylums was not always gentle: shock treatments, confinement, purging, and physical restraint were common practices in the struggle to find a cure for insanity.

The great pioneers of psychiatry, including Benjamin Rush (1745–1813), Henry Maudsley (1835–1918), and Emil Kraepelin (1856–1926), set in train a change of thinking, emphasizing the need for medical understanding and treatment of the mentally disordered. The influence of such innovative thought, coupled with growing social reaction against the conditions in the asylums and the discovery treatments such as psychoanalysis for mental disturbance, culminated in the birth of the psychiatric hospital. While present-day enthusiasm for care in the community has led to a diminishing of the role of the psychiatric hospital, it is nevertheless the case that many people with mental disorder are cared for in psychiatric hospitals.

Table 1 Typical subjects found in UK psychologists' court reports

Posttraumatic stress disorder
Compensation
Childcare
Suitability for treatment
Fitness to plead/stand trial
Reliability of witness statements
Reliability of confessional evidence
Diminished responsibility

So it transpired that the mentally ill became the property of the medical profession: as psychiatry found a professional identity, so psychiatrists were seen as the experts on the assessment and treatment of mental disorder.

In law, the insane have traditionally been accorded a special status in that it is accepted that they should not be punished for criminal acts. The reasoning behind this status is plain: the concept of *mens rea* holds that if a person is to be held responsible for his or her actions, then it must be the case that in committing a crime they have acted of their own free will. Can it be said that the mentally ill are responsible for their actions, including criminal acts? There are two legal cases which were highly influential in formulating an answer to this question.

James Hadfield (1771/1772–1841) was a soldier in the Duke of York's bodyguard who received sabre-inflicted head wounds when fighting in the Battle of Lincelles, Flanders, in 1794. From accounts of the case, it is evident that Hadfield must have suffered brain damage which, in turn, precipitated bouts of mental instability. It was said that during these bouts of insanity he would threaten the life of his child because God so commanded; he would also say that he must die to save the world, yet he must not kill himself. An individual making such a presentation would now be seen as exhibiting delusions following his/her head injury.

Hadfield devised a plan that would bring about his death: he would assassinate the monarch, King George III, for which the penalty would be execution. In 1800 he made his attempt, firing a pistol at the King as he entered a theater. His shot missed and Hadfield was captured by bystanders, charged with high treason, and eventually brought to trial. Alongside the growing awareness at that time of the plight of the mentally ill, Hadfield's case attracted widespread public sympathy, particularly given his standing as a British soldier wounded in battle.

During Hadfield's trial, his defense, delivered by Thomas Erskine, sought to refine the arguments with respect to the legal standing of the individuals with a mental illness. Erskine could not apply the so-called 'wild beast test' as Hadfield was clearly lucid and able to comprehend the court proceedings. Instead, Erskine used a more subtle approach, advancing the argument that Hadfield's delusions at the time of the offence must be taken into consideration: if the court agreed that Hadfield was deluded at the time of the assassination attempt, then, Erskine argued, he cannot be considered guilty of a crime. Medical and lay evidence was called to support the defence's position regarding Hadfield's madness. Erskine's strategy worked and the Lord Chief Justice halted the trial, directing the jury to find Hadfield not guilty "he being under the influence of Insanity at the time the act was committed."

This judgment had two important consequences: first, it created a new class of offender, then called 'criminal lunatics' (now generally referred to as mentally disordered offenders); second, it created a practical problem: if Hadfield was not a criminal, then it followed that he could not be sent to jail; nonetheless, if Hadfield was judged to be a danger to the public, some form of secure detention was required to protect society. As will be seen presently, the solution to this dilemma was an important one in the development of forensic psychiatry. However, turning to the second important legal case, the name of Daniel McNaughton (spelt M'Naghten in some texts) comes to attention.

The case of Daniel M'Naghten (1813–65) is generally taken to be the beginning of mental health legislation in England with regard to criminal acts. The name M'Naghten is variously spelt in different sources where it appears as McNaughton, M'Naghten, M'Naughton (as in the original trial report), McNaughton and McNaughten (as in the records from Bethlem and Broadmoor Hospitals), while the family spelling was McNaughtan and the one known example of M'Naghten's signature supports the spelling McNaughtun.

On the basis of case records dating back to the 1840s, it is highly likely that McNaughton was suffering from paranoid schizophrenia; specifically he believed that he was being persecuted by both Catholic priests and the Tories. His delusional beliefs led him to the decision that to end his persecution he would kill the Tory Prime Minister, Sir Robert Peel. In 1843, McNaughton made his attempt on the life of the Prime Minister but, through mistaken identity, shot and killed the Prime Minister's private secretary. McNaughton was arrested at the scene of the crime and sent for trial. The weight of eminent medical opinion at the trial was that McNaughton was insane and the jury returned a verdict of not guilty on grounds of insanity. However, McNaughton's insanity was not of a florid type leading to obvious loss of control: it was clear from his own statements that he knew very well what he was doing at the time of the crime, acted deliberately, and was fully aware of his actions and their consequences. Despite McNaughton's plea that he was driven by his persecutions, it was the calculated quality of the seemingly cold-blooded killing that brought about a wave of public protest after the trial. Accordingly, leading judges of the day were asked to inform the government on the interpretation of the laws of the land with regard to the legal position for cases of insanity and crime. The judges formulated the McNaughton test, or McNaughton rules as they are sometimes called.

The McNaughton test, given several caveats, embodies several key principles. First, everyone who stands before a court is to be presumed sane and responsible unless proven otherwise. Second, an insane person is punishable if he or she knew at the time of the offence that the act was wrong. Third, to establish an insanity defence it must be proved that at the time of the offence the accused did not know the nature of the act; or if they were aware of their actions, then they did not know that their actions were wrong. Thus, to establish an insanity defence the test is, does the accused know the nature of the act? If the accused do know the nature of the act, do they know it is wrong? These are powerful questions demanding special skills and knowledge to provide answers: some members of the medical profession of the day began to specialize in understanding the criminal lunatic so as to inform the courts on just such matters.

As the courts began to grapple with the implications of cases such as Hadfield and McNaughten, the issues they raised were not just legal but were also practical in nature. If such people were not criminals, could they be sent to jail? If they were judged to be dangerous, could they be released into the community? The judge in the Hadfield case did send Hadfield to jail but expressed doubts about his authority to do so under the law of land. Thus, a series of parliamentary acts dating from 1800 onward began to put in place legislation to allow criminal lunatics to be admitted to asylums for the mentally ill.

Hadfield was taken from jail and admitted to Bethlem Hospital in London but he was not a model patient: he killed another patient and escaped from the Hospital, spending time at large before his recapture and return to Newgate Gaol. This type of incident led to the view that asylums were being asked to admit patients for whom the facilities, personnel, and buildings alike were not suited.

This concern led to the development of hospital 'criminal wings': these wings were secure, with locks, bolts, and bars, but staffed by doctors and nurses to treat those detained. In 1816, Hadfield was admitted to the criminal wing at the Bethlem Hospital where he remained until his death in 1849 when he was 70 years of age. However, by the late 1850s, further concern was expressed about the levels of security and safety on these wards and the standard of treatment which they offered. Thus, in 1860, building of Broadmoor Criminal Lunatic Asylum in Berkshire began. Broadmoor opened in 1863 and began receiving its first patients, decanted from the criminal wings of hospitals, to fill its 500 beds.

Broadmoor was the first of a series of high-security institutions for the criminal lunatic; Rampton Hospital followed in 1914, then Moss Side in 1933, and finally Park Lane in 1974 (the latter two being amalgamated in 1990 to form Ashworth). Carstairs Hospital in Scotland performs a similar function (also accepting patients from Northern Ireland). Legislative changes gave these institutions the generic title of Special Hospital, and they are charged with detaining mentally disordered offenders under conditions of maximum security. Moving to recent times, a new wave of services has developed which offer treatment for mentally disordered offenders in settings of medium and low security as well as in the community.

As services expanded, so the importance of understanding and treating the criminal lunatic grew and the specialism of forensic psychiatry developed accordingly. The growth in forensic expertise can be seen in the increasing refinement of mental health law, academic study of the relationship between mental disorder and criminal behavior, specialist assessment of the individual to inform the court, risk assessment of the danger posed by an individual, and the growth in sophistication in design, running, and evaluation of services for the mentally disordered offender. Similar developments are to be seen in North America and many other countries.

Current Practice

Forensic Psychology

What expertise might a forensic psychologist be able to offer the court with respect to the evidence placed before it? First, the psychologist can present the findings of empirical psychological research on the strengths and weaknesses of different types of evidence, for example, there is a body of research on both eyewitness evidence and confessional evidence; second, the psychologist may give an expert assessment on a given case. Lionel Haward has described four roles that the forensic psychologist might take when acting as an expert witness.

Actuarial role

In this role, the forensic psychologist draws on statistical information to give evidence regarding the probability of an event.

For example, the psychologist may provide actuarial evidence regarding the sequelae of a psychological trauma and its impact on social functioning.

Advisory role

The psychologist may provide an opinion before or during the trial on another expert's report, advising on the accuracy of the report and which issues to focus on when the report's author is under examination.

Clinical/assessment role

In this role, the forensic psychologist presents the court with evidence regarding an individual's state of mind as with, for example, the presence of psychological disorder or dysfunction. Haward extends this role to include the assessment of normal human functioning: for example, Gudjonsson and Haward note a case in which it was important to establish that the accused was left-handed and findings from a series of observational, neurological, and psychological tests were used to present evidence to the court regarding this matter.

Experimental role

The credibility of evidence presented in court may hinge on whether human performance under given conditions is likely to be accurate. Could a witness have really seen a face under low levels of light? Is it possible to make accurate judgments of another car's speed when traveling in a moving vehicle? Such questions are open to experimental investigation by simulating the conditions at the time of the incident and testing performance thereby giving the court an empirically informed statement of the reliability of evidence in a given case.

Forensic Psychiatry

The role of the forensic psychiatrist in court, although reflecting a different professional perspective, may be identical to those defined by Haward for the forensic psychologist. Thus, forensic psychiatrists might draw on the research on the relationship between mental disorder and criminal behavior to inform a given case. Alternatively, a forensic psychiatrist might be called on to give an expert opinion with respect to an individual's fitness to stand trial, or formulate a risk assessment with regard to, say, releasing a patient from secure conditions into the community, or to inform the court with respect to the treatability of an offender.

Concluding Comment

While there are differences between forensic psychology and psychiatry, the complexity of the issues involved mean that when the two disciplines come together, alongside other professions such as forensic nurses, probation officers, and the police, they are at their most effective.

Glossary

Actus reus The guiding principle in law, which dates back to the jurist Sir Edward Coke (1552–1634), when deciding if a crime has taken place is that “An act does not make a person guilty unless (their) mind is also guilty,” *actus reus*, which literally means ‘guilty act,’ is the external element of a crime and is taken to be a bodily movement. The internal element of a crime lies in the intent of the actor to do wrong, the ‘guilty mind’ or *mens rea*.

DSM The *Diagnostic and Statistical Manual of Mental Disorders* (DSM) is published by the American Psychiatric Association. It presents standard criteria for the classification

of mental disorders and is used in the United States of America and other parts of the world by academic researchers, clinicians, health services, insurance companies, and policy makers. A ‘text revision’ of the DSM-IV, DSM-IV-TR, was published in 2000 which gave additional diagnostic information.

Mens rea Literally, ‘guilty mind’ (see *actus reus*).

Risk assessment The process of estimating (using actuarially derived parameters or professional judgment) the likelihood, or risk, of an event occurring.

Risk factors The variables that predict the likelihood of a given criterion of risk occurring.

The subject matter of forensic psychiatry lies in the application of psychiatric knowledge to offender populations with respect to the juxtaposition between mental disorder and criminal behavior. The majority of offenders are not mentally disordered; however, some offenders (generally called *mentally disordered offenders*) do have a diagnosable mental disorder and this group is of particular concern to forensic psychiatry.

The starting point in discussing mental disorder and crime lies in the legally accepted definition of mental disorder. In general psychiatric practice, a mental disorder is diagnosed by reference to a formal diagnostic system, such as the American Psychiatric Association’s *Diagnostic and Statistical Manual of Mental Disorders*. For the purposes of law, however, a legal definition of the term mental disorder is required: for example, in England and Wales, the Mental Health Act 2007 states that the types of mental disorders to be considered by the court in criminal cases are mental illnesses (such as schizophrenia, bipolar disorder, anxiety, or depression), personality disorders, eating disorders, autistic spectrum disorders, and learning disabilities. However, a brain disorder or disability is *not* taken to be a mental disorder unless it also gives rise to a disability or disorder of the mind. It is also the case that new types of disorder can be introduced: the advent of dangerous and severe personality disorder was an initiative aimed at those whose level of violence (including sexual violence) posed a significant danger to the community.

There are two points to note with regard to mental health legislation. First, legal definitions may vary by location: in other words, different jurisdictions may well have different definitions of mental disorder. Second, definitions of mental disorder do not remain constant over time within the same jurisdiction: for example, in England and Wales, the 2007 Act made some significant changes to the preceding 1983 Act. The shifts and changes in definition of the term mental disorder for legal purposes also introduce an element of discord with formal psychiatric diagnostic systems, which themselves may change according to time and place. The net result of these variations is

that in a given case, forensic psychiatrists must work with the courts in deciding upon issues of mental disorder.

The overlap between mental disorder and criminal behavior has concerned criminologists, lawyers, and psychiatrists for many years. For a crime to be committed in law, there must be two elements, *mens rea* (guilty mind) and *actus reus* (guilty action): the former may be thought of as the intention to commit an act while knowing it was wrong; the latter as the act (or failure to act, as in negligence) itself. Thus, the act may be committed but unless there can be shown to be *mens rea*, guilty intent, there is no criminal case to answer. The obvious example of this principle in action lies in the notion of an age of criminal responsibility: a child may commit a serious act but we accept that because of their age they cannot legally be held responsible for their actions and so cannot be said to have committed a crime. In other words, for those not judged to be responsible for their actions, there can be said to be *actus reus* but not *mens rea*. Since the trial of Daniel M’Naughten, the law has evolved to take account of the view that the ‘mad’ or mentally disordered cannot be said to have *mens rea* and so cannot be held responsible for their actions.

It is intrinsic to the fairness of the legal system that it does not penalize those members of society, such as children under the age of criminal responsibility, who are not aware of the consequences of their actions. An individual who is mentally disordered, within the legal understanding of that term, may fall into the category of those for whom *mens rea* is absent. When *mens rea* is absent, the individual cannot be said to have committed a crime and is accordingly dealt with under Mental Health legislation rather than criminal law. It follows that the imposition of sanctions that may ordinarily follow a crime, such as imprisonment, are not appropriate for the mentally disordered individual. The court may order that the mentally disordered offender receives treatment which, depending on the risk the individual poses to the wider community, is to be delivered in various settings ranging from the community to low, medium, or high security.

From the wide range of concerns of forensic psychiatry, three areas have been selected for discussion as they encapsulate issues at different legal stages with regard to the mentally disordered offender. These three topics are: (1) assessment of competence prior to committal; (2) risk assessment with respect to placement; and (3) treatment during placement.

Assessment of Competence

The practical difficulty in the case of the mentally disordered offender lies in establishing whether at the time that they committed the act the accused was aware of their actions and, if so, whether they knew that their act was wrong. In cases of mental disorder, it falls to the defense to mount an *insanity defense*; that is, to plead that the accused is, in fact, not guilty by reason of insanity at the time the act was committed. There are variations on this theme across different legal systems; however, the task of the forensic psychiatrist remains broadly the same in such cases. That is, the psychiatrist must look back – ‘postdict’ rather than predict – to give a professional opinion of the accused’s state of mind at the time of the crime. Given that there may be months or even years between the act and the need for a ‘psychiatric postdiction’, it is clear that such assessments can never be an exact science.

While the moral and legal issues are similar with respect to competency to stand trial (variously referred to as ‘unfit to plead’ or ‘under disability’), the practical task facing the forensic psychiatrist lies in the present rather than the past. In England and Wales, for example, the legal test of fitness to plead is that the accused is unable to comprehend the course of proceedings of the trial so as to make a proper defense, to know that he or she might challenge any jurors, and to comprehend the evidence or give proper instructions to his or her legal representatives.

It falls to the forensic psychiatrist to inform the court whether the accused is mentally disordered, within the legal meaning of the term. There are several protocols that have been developed to aid assessment of competency, such as Competency Screening Test and the Georgia Court Competency Test. It is unlikely, however, that these instruments will replace the traditional clinical skills of the forensic psychiatrist.

Risk Assessment

A risk assessment is an exercise in prediction, an estimation of the likelihood that some future event will occur. The estimation of risk is required in many areas of life: financiers estimate the risks of their investments, insurers estimate the risks of fire, theft, and car accidents, and surgeons estimate the risks of operations. When sanctioning the treatment of a mentally disordered offender, a prime concern lies in the risk the offender poses to the community. Is it safe to allow the individual to attend a local hospital to receive the necessary treatment or is the risk too high that they will inflict further harm? If there is a risk of harm, what level of security is required? In making decisions about this type of risk much is at stake should the

Table 1 Hits and misses in prediction

	<i>Actual Yes</i>	<i>Actual No</i>
Predict Yes	True positive (Hit)	False positive (Miss)
Predict No	False negative (Miss)	True negative (Hit)

individual reoffend. Of course, continued offending includes both the human costs endured by further victims and the financial costs of being associated with police, courts, and so on. In this light, the assessment of the risk posed by the mentally disordered offender is highly important.

As shown in **Table 1**, in practice, forensic practitioners are faced with a classic decision outcome matrix.

To illustrate the processes involved, consider processes in making the decision whether or not to send a violent mentally disordered person to a maximum security hospital. It is the role of practitioners to predict whether the level of risk of that person being a continued danger to the public is such as to justify detaining that individual for treatment in conditions of high security. Suppose the psychiatrist predicts Yes and, indeed, had the individual stayed in the community, there would have been more victims (actual Yes); then a decision to admit to hospital is correct (a Hit) and the public will be protected. However, suppose the prediction is Yes but in fact the individual would not have been a continued danger to the public (actual No). Now the person will wrongly be admitted to conditions of security (a Miss), with all the attendant issues with respect to human rights and public spending. Alternatively, suppose the practitioner predicts No and the person is not detained but then commits further serious offenses in the community (actual Yes): such instances (a Miss) are highly likely to attract the popular media and the scene is set for a public inquiry. Finally, the prediction may be No and the individual remains in the community and does not reoffend (actual No) which is a good decision (a Hit).

These same processes repeat themselves at other times in the mentally disordered offender’s route through the secure system as, for example, at the point of making decisions about an individual’s release from high security to less secure conditions.

The Terminology of Risk Assessment

The *criterion of risk* is a basic term in risk assessment: it refers to an exact description of the event that is being assessed. For example, in physical medicine, the criterion of risk might be the occurrence of heart disease or cancer, or even particular forms of illness such as angina or breast cancer. Once the criterion of risk is set, then in order to estimate risk in a given case, the associated *predictors* (or *risk factors*) must be identified. Thus, for the criterion of heart disease, the predictors may include a family history of heart disease, a history of smoking, a pattern of unhealthy eating and lack of exercise, a high cholesterol level, high blood pressure, and a stressful occupation. It is important to emphasize that the presence of these predictors does not mean that the realization of the risk is inevitable. Rather, the presence of a predictor increases the

likelihood that the event will occur, recognizing that some predictors carry more weight than others. Further, it is generally the case that the greater the number of extant predictors in a given case, the greater the risk becomes. Thus, an individual with a family history of heart disease, who smokes 20 cigarettes a day and has high blood pressure, is more likely to suffer a heart attack than another individual who has a moderately high cholesterol reading. The important word here is *likely*: for neither of these individuals is a heart attack certain, but the risk would certainly be seen as higher in the former compared to the latter.

The identification of predictors of risk is not a simple task. The issue-facing practitioners is how to know exactly what aspects of an individual's history and current functioning should be of concern in order to estimate a given risk. The research literature traditionally makes the distinction between *static* predictors of risk and *dynamic* predictors of risk.

Static risk predictors are historical or background factors, the presence of which is known to elevate the risk of a given criterion. In the example above, a family history of heart disease would be a static risk predictor for heart disease. Again, the presence of static predictors, which by definition cannot change, do not mean that the event is predetermined: the presence of static predictors simply raises the probability of the event happening in the future. Dynamic risk predictors are aspects of an individual's current functioning: thus, smoking, an unhealthy diet, and a stressful job are all dynamic risk factors in relation to heart disease. In practice, it is often a combination of static and dynamic predictors that gives the strongest basis by which to predict risk.

In summary, when completing a risk assessment system, it is crucial to have clearly defined risk criteria. Once the risk criteria are set, the appropriate risk predictors can then be identified and a method of assessment put into place.

Methods of Risk Assessment

The classic distinction with respect to the method of risk assessment lies in *clinical* and *actuarial* prediction.

Clinical prediction

In clinical prediction, the assessment of risk is based on professional judgment by an individual practitioner, a clinical team, or a case conference. The accuracy of the prediction relies on the clinical knowledge and experience of those involved.

Actuarial prediction

Actuarial risk prediction uses statistical methods to identify the risk factors for a given criterion. The statistically identified risk factors may then be combined into an algorithm to produce a standardized risk assessment, typically in the form of a questionnaire that guides the assessor through the necessary steps to arrive at an assessment of risk. In developing a system of actuarial risk assessment, the first step is to identify the risk predictors for the given criterion. Initially through the use of clinical records, case material, and the research literature, potential risk factors are identified for the criterion of concern. The second step is to identify an appropriate cohort and measure all the previously identified potential risk factors. The cohort is then followed over a lengthy period (typically years)

Table 2 Actuarial predictors of violent recidivism

1. Level of victim injury in index offense
2. Never married
3. Female victim-index offense^a
4. Failure on prior conditional release
5. Property offense history
6. Age at index offense
7. Alcohol abuse history
8. High score on psychopathy checklist
9. DSM-III personality disorder
10. Separation from parents under age 16
11. Victim injury in index offense^a
12. DSM-III schizophrenia

^aThese factors are contraindicative of recidivism: that is, their presence suggests that violent recidivism is less likely.

Source: Webster et al., 1994.

to establish which potential risk factors actually best predict the occurrence of the criterion of risk.

A good example of an actuarial to risk assessment is seen in research conducted in Canada concerned with the development of a scale for assessing the risk of violent recidivism in mentally disordered offenders. The cohort in this study consisted of more than 600 males treated in a maximum security psychiatric hospital. After a mean time at risk of almost 7 years, the cohort was divided into those individuals who were and were not violent recidivists. These two groups could then be compared across a range of demographic, clinical, and offense-related measures, with the aim of determining statistically what particular factors differentiated between the two groups and hence predicted violent recidivism. As shown in [Table 2](#), 12 predictors of violent recidivism were identified using statistical methods: these factors are efficient in that they maximize the likelihood of making a 'hit' and minimize the likelihood of a 'miss.'

In order to make their research available for clinical practice, Christopher Webster and his colleagues produced *The Violence Prediction Scheme* to be used in assessing the likelihood of violence by high risk men. *The Violence Prediction Scheme* presents practitioners with full details on assessing the various predictors and producing an estimate of the risk of violent recidivism. This instrument is designed for use with high risk *men* and therefore so it should not be used with other populations, say women or young offenders, where quite different predictors of violence may be involved.

The same procedure can be followed for other criteria: sex offending in mentally disordered populations is an obvious concern and actuarial studies have identified several predictors of sexual recidivism. Another Canadian study, by Vernon Quinsey and his colleagues, reported that rapists presented a greater risk of recidivism than sex offenders against children. As shown in [Table 3](#), they identified a range of predictors of sexual offending.

There is now a great deal of research conducted on actuarial risk assessment with mentally disordered offenders, enabling increasingly fine-grained and sensitive assessments to be made. This research had led to the development of instruments such as the Classification of Violence Risk and the Historical-Clinical-Risk Management-20.

Table 3 Actuarial predictors of sex offense recidivism

1. Never married
2. Violent convictions
3. Admissions to corrections
4. Previous sexual convictions
5. Previous female victims
6. Previous male child victims
7. Deviant sexual interest
8. High score on psychopathy checklist

Source: Quinsey VL, Rice ME, and Harris GT (1995) Actuarial prediction of sexual recidivism. *Journal of Interpersonal Violence* 10: 85–105.

There is a long-running debate regarding the relative efficacy of clinical and actuarial prediction. Those who favor actuarial methods note the scientific basis and superior accuracy of statistical prediction; proponents of clinical methods argue for the skill of the clinician in making individually based risk assessments and against extrapolating from broad-based research findings to the individual patient.

Treatment and the Mentally Disordered Offender

Alongside court work, the treatment of mentally disordered is a mainstay of forensic psychiatry services. Such services can be delivered in the community, in hospitals (both open and secure), and in prisons. The task of those offering treatment to the mentally disordered offender is complex. Alongside an awareness of risk to the public, and in some cases the need to work within conditions of security, treatment has the twin aims of ameliorating the disorder while also lowering the risk offending. It is not always the case that these two aims are synonymous.

Take, for example, the case of a person with schizophrenia prone to angry outbursts and associated acts of violence. The treatment must both reduce the symptoms of the schizophrenia and help the individual learn to control their anger in order to reduce the risk of violent behavior. In practice, treatment may well involve a combination of psychotropic drugs to treat the schizophrenia and psychological methods to address anger and violent behavior. The Violent Offender Treatment Program (VOTP) provides an example of this approach.

Violent Offender Treatment Program

The VOTP was designed for mentally disordered offenders in high security and uses a combination of individual and group work set against a background of medication as appropriate to each patient. After a comprehensive assessment using the patient's files, clinical interview and observation, and psychometric scales, patients begin the program. In order to learn to control their anger and violent behavior, patients learn first to analyze the situations that lead them to become angry, then learn strategies to manage their thoughts and emotions, and develop skills to communicate and negotiate more effectively so as to reduce interpersonal conflict. The evaluation of the VOTP program indicates, that is, successful in bringing about change.

Conclusion

While relatively few in number compared to mainstream offenders, the mentally disordered offender is of great public concern and sets many challenges for forensic psychiatry. The complexities of the moral and legal issues with respect to responsibility, the intricacies of assessment, and the problems of treatment are all issues that are sensitive to changes in law, social policy, and clinical practice.

Glossary

Coerced confession A coerced confession is a suspect's formal admission of guilt under conditions of duress.

There are two types of coerced *false* confession:

(i) *coerced-compliant* where the suspect makes a confession knowing that it is false; (ii) *coerced-internalized* where during interrogation the suspect comes to believe that the official version is correct and their own memory is wrong.

Cognitive interview A method of interviewing witnesses that use prompts and retrieval techniques based on the psychology of memory.

Error of commission An error of commission occurs when a witness mistakenly introduces into their testimony something which they did not see at the time of the incident.

Error of omission An error of omission occurs when a witness fails to recall something they had observed at the time of the incident.

Interrogative suggestibility *Suggestibility* is the extent to which an individual is compliant with commands, instructions, or orders from another person: high levels of suggestibility (as with hypnotic suggestibility) are not common. *Interrogative suggestibility* refers to the degree to which people will come to accept as true the messages conveyed by the interrogator during formal questioning.

Leading question A question that has the potential to mislead a witness by presupposing the answer or by providing misleading information.

Mock jury study An experimental methodology intended to replicate and so allow the study of the processes which take place when a real jury is deliberating in a criminal trial.

At the turn of the twentieth century, a number of pioneers, including G.F. Arnold, Guy Whipple, and Hugo Münsterberg, began exploring the potential of applying emerging psychological knowledge to the workings of the legal system. Indeed, as long ago as 1908, Hugo Münsterberg set the agenda for future generations of forensic psychologists in nominating the reliability of evidence and the workings of the courtroom as the main concerns of forensic psychology. Since that time, forensic psychology, sometimes called *legal psychology*, has become a specialty in its own right, although maintaining a central concern with evidence and the courtroom.

The Psychology of Evidence

Eyewitness Testimony

The involvement of psychologists in understanding the accuracy of eyewitness testimony provides an example of the interplay between psychological theory, applied psychological research, and real-life decisions in the courtroom. The fallibility of human memory lies at the heart of a catalog of wrongful convictions influenced by eyewitness testimony. While the pioneers raised the issue, it is research from the 1970s onward which has greatly enhanced understanding of the factors that may influence the accuracy of eyewitness memory.

The functioning of human memory can be conceived as having three stages: first, the perception or *acquisition* of information about the world; second storing or *retaining* the perceived information; third the process of *retrieval* or remembering stored information. In the context of witnessing an incident these stages become: (1) seeing the incident; (2) the period before giving evidence; and (3) giving evidence. As can be seen from Table 1, a range of factors are related to

the accuracy of eyewitness memory (including both recall of what happened and facial identification of the suspect). Further, within these three stages there are different kinds of variables to consider: these variables can be classified as *social*, that is, to do with interactions between people; *situational*, that is, concerning the setting in which the event occurred; *individual*, as with the characteristics of the individual witness; and *interrogational*, that is, regarding the process of eliciting testimony.

The following sections provide examples of the way in which research has investigated the influence of different variables at each of these three stages.

Acquisition: nature of the witnessed incident

The effect on memory of the nature of the witnessed incident has been investigated in several studies which consider the impact of witnessing an incident which is violent in nature. As seen in a study reported by Elizabeth Loftus and her colleagues, such violent incidents may include scenes of physical assault and the presence of weapons. In the Loftus study, separate groups of observers saw different versions of a filmed bank robbery: in one version shots were fired but no one was hit; in the other version, a small boy was hit and was seen bleeding from a head wound. Those witnesses who saw the violent scenes gave less accurate recall of the incident. This finding has been replicated in several studies leading to the broad conclusion that memory is significantly better for the nonviolent rather than violent incidents. However, it is likely that the degree of violence is important: less threatening events that engage the witness's attention in a stimulating manner may produce satisfactory memories for the event. Further, there is the phenomenon of 'weapon focus' where witnesses' attention is directed at the knife or gun to the exclusion of other details about those involved and what happened.

Table 1 Variables in eyewitness memory research

<i>Social</i>	<i>Situational</i>	<i>Individual</i>	<i>Interrogational</i>
Attitudes	Complexity of event	Age	Artists' sketches
Conformity	Duration of event	Alcohol use	Computer images
Prejudice	Illumination	Cognitive style	ID parades
Status of Interrogator	Time delay	Personality	Mugshots
	Type of crime	Race	Instructions
Stereotyping	Target factors	Sex	Photofit
	Weapon		Training

Retention: discussion between witnesses

In instances where there is more than one witness to an incident, should witnesses be allowed to discuss events before giving their testimony? The research evidence suggests that group discussions can lead to a more complete description of an event but at the price of introducing a source of error. While having the potential to prompt memory and lead to fuller recall, discussions can also bring about errors of commission: that is, errors may be introduced which are related to items which were *not* seen in the original incident. Further, group dynamics may influence witnesses to change their testimony to agree with other members of the group. On balance, it is a moot point whether discussion between witnesses is desirable in the interest of producing accurate testimony.

Retrieval: leading questions

A body of research, perhaps most notably influenced by the American psychologist Elizabeth Loftus, has shown how even the most subtle changes in question wording can influence witness testimony. Another study by Loftus and her colleagues provides an excellent example. Witnesses to a filmed automobile accident were asked to give estimates of the speed of the cars when 'they – into each other': different groups of witnesses were asked this question with the verb being one of 'contacted,' 'hit,' 'bumped,' or 'smashed'. The witnesses' estimates of the speed increased, following the order given above, from 31.8 to 40.8 mph. Further, when later questioned, the witnesses who had been asked about the 'smash' were more likely erroneously to say that there was broken glass at the scene of the accident.

Witnesses can also incorporate misleading information into their testimony: in another study by Loftus, observers were asked to judge the speed of the car 'as it passed the barn,' although no barn had been seen. One week later, the observers were asked a set of questions about the film, including whether they had seen a barn: more than 17% of the 'primed' observers said that they had seen the fictitious barn.

The effects of misleading information are most likely to be found when the source of the information is seen to be of high status, or if the witness thinks the police have special knowledge about the incident, or if the misleading information relates to peripheral detail rather than central events.

Witness factors

Witness factors such as age, intelligence, personality, anxiety, and sex, are active across all three stages of memory although the research evidence does not suggest that they have any

consistent effect on the accuracy of eyewitness memory. However, there are two exceptions to this general conclusion: the first is the evidence regarding the relationship between witness confidence and accuracy which suggests caution in that confidence in the accuracy of one's memory is *not* an index of accuracy; the second is the body of work on children as witnesses which shows that with sensitive, age-appropriate questioning, even young children can be reliable witnesses.

Confession Evidence

If a person confesses to a crime, this surely is an admission of guilt that is beyond dispute. While people unconnected with a case do come forward and make a *voluntary false confession*, the police investigation often shows beyond doubt that such admissions are fake (although a great deal of police time may be wasted investigating this type of confession). Voluntary false confessions are sometimes given by people seeking attention or who are psychologically distressed. On other occasions, suspects will knowingly give a false confession (called a *coerced-compliant false confession*) during police interrogation: they may do this to free themselves from the stress of interrogation or to protect another person. Such false confessions are given in the (sometimes mistaken) belief that the police investigation will inevitably show that their confession is untrue.

In the examples given thus far, the individual, unless severely disturbed, is aware that their confession is false. The phenomenon of the *coerced-internalized false confession* is seen when the suspect's own knowledge of the truth actually changes during interrogation so that they come to agree with the interrogator's version of what happened. How can such a transformation in memory take place? In order to understand the coerced-internalized false confession, it is necessary to consider the characteristics of both the interrogation and the suspect.

The forensic psychologist Gisli Gudjonsson has played a significant role in helping to understand the processes that produce false confessions. Gudjonsson suggests that the suspect under interrogation is taking part in a highly unusual 'closed' social interaction: interrogation occurs in a closed room, the suspect is closed off from their normal surroundings, and the suspect's attention is closed in on the interrogator. Further, the interrogator holds the balance of power and therefore controls all aspects of the interaction. Trained in interrogational techniques based on the psychology of persuasion, the interrogator's focus is on gaining a confession from the suspect.

Gudjonsson suggests that some suspects will cope with the stress of interrogation by actively dealing with the situation and resisting the pressure to confess. However, other suspects will become passive and take a helpless stance, seeking to avoid confrontation with the interrogator and reducing their emotional stress. Suspects who react in this passive way may be overly *suggestible* with regard to the interrogator's persuasive tactics. The concept of suggestibility has a long history in psychology: in 1900, Alfred Binet wrote *La Suggestibilité*. Since then books and journal articles on the topic have regularly appeared in the psychological literature. In the context of an interrogation, *interrogative suggestibility* is the extent to which people will come to accept as true the messages conveyed by the interrogator during formal questioning. Thus, both publicly and privately, the suggestible suspect comes to agree with the account offered by the interrogator even though it differs from their own memory for events.

Some individuals would be more susceptible than others: Gudjonsson and his colleagues have shown that interrogative suggestibility is related to poor recall of the original event (perhaps because of intoxication at that time), low self-esteem, low intelligence, high emotionality, and anxiety, and a high need for social approval. The overall picture which emerges is that situational cues, interrogational pressure, and the suspect's characteristics can all interact and increase the likelihood of a false confession.

Psychology in the Courtroom

The psychological study of courtroom processes covers a great deal of ground, spanning both criminal and civil courts, and incorporates diverse areas of law including juvenile and family law, mental health law, discrimination law, and competency to stand trial. However, the study of the jury lies at the heart of this area of forensic psychology.

The jury is a natural topic for psychological research: the jury must listen to and evaluate evidence, each juror must formulate their personal opinion regarding the accused's guilt or innocence, and then the jurors meet to discuss the evidence and reach a collective decision. The cognitive and social processes involved in coming to a decision are critical for justice to be done but there is a problem in conducting jury research. For obvious reasons, it is not ethically permissible that studies of jurors are conducted during trials, nor in some jurisdictions is it permissible to interview and seek to debrief jurors after a trial. Thus, a great deal of knowledge of jury and juror behavior comes from, so-called, 'mock jury' studies in which controlled simulations of trials are conducted and 'mock jurors' are closely observed while key variables are introduced into proceedings.

Extra-Evidential Influences

The evidence presented in the courtroom should inform jury decision making; however, there is a concern that jurors can be influenced by various extra-evidential influences including pretrial publicity, witness confidence, and their own and other jurors' sentiments and prejudices.

Pretrial publicity

In typical studies, the decisions of mock jurors exposed to publicity are compared with those of other mock jurors who are not subject to such influences. Thus, mock jurors may be shown newspaper cuttings containing details about, say, a defendant's criminal record or their retracted confession. When compared to mock jurors who read newspaper stories which did not contain the biasing details, the 'exposed jurors' are more likely to return a guilty verdict after a mock trial. In real-life, judges can instruct jurors to ignore pretrial publicity, but this is probably easier to say than to do. In practice, the selection of jurors not exposed to the pretrial influence is the optimum strategy to select a fair jury although, once again, this is probably easier said than done.

Witness confidence

Is a highly confident witness more likely to be believed by jurors than an uncertain witness? The experimental evidence certainly suggests that mock jurors are more likely to be persuaded by testimony from confident witnesses and so return a guilty verdict. Conversely, jurors place less credibility on the testimony of the less confident witness. Given that, as noted previously, witness confidence is not always a reliable index of accuracy; a belief in a positive relationship between confidence and accuracy is not necessarily a good thing.

Interpersonal perception

Are jurors influenced by emotion, sympathy, and prejudice? For example, the perceived physical attractiveness of the defendant can lead to a favorable outcome but an attractive defendant with no justification for their offense may be seen in a more severe light. Similarly, defendants of high socioeconomic status may be seen as less blameworthy for their offense; while a gender bias suggests that females are less likely to be found guilty for reasons of insanity. Finally, children are seen to be less reliable witnesses in court than adults (which may not be the case). However, the evidence gathered from real jurors suggests that jurors' decisions are not greatly influenced by the perceived characteristics of victims and defendants.

Jurors

Juror Selection

There are formal selection criteria for jury service, such as age and eligibility to vote and as if they satisfy these criteria any individual may be called for jury service. Nonetheless, objections may be raised in specific cases: for example, an individual with a known prejudice against another group of people would not make impartial jurors in certain trials. It is prudent therefore to allow the 'screening out' of unsuitable jury candidates on a trial-by-trial basis. In practice, screening procedures are concerned with prospective jurors' exposure to pretrial publicity of the case in hand, their attitudes toward the offense being tried, and whether they know anyone involved in the case.

The selection of jurors is often an emotive issue, taking a great deal of the court's time, and raising the ethical issue of whether this process should use scientific jury selection, informed by psychological assessment. The proponents of

scientific selection argue for an empirically based method of selecting jurors; opponents hold that selection is unsafe and contrary to the principles on which the jury system stands.

Juror Competence

Jurors may be required to assimilate a range of evidence presented during the trial and to understand the judge's presentation of the issues before they reach a verdict. Several studies have looked at juror comprehension of the evidence and understanding of judges' instructions in complex cases. The typical finding, perhaps not unexpectedly, is that some jurors can struggle to make sense of the proceedings and to evaluate the finer points in the case made by the prosecution and the defense.

Reaching a Verdict

The real process of jury deliberation during a trial is impossible to research at first hand. The nearest that can be achieved is either to observe mock jury deliberations, or (where allowed) to interview jurors after a trial. The extant research alludes to the group dynamics of structure, process, and decision making by 12 people thrown together in a highly charged situation. The jurors must appoint a leader, poll views, debate the evidence, recount the judge's instructions, and seek to apply the law to the evidence. Thus, the jurors may well be in a state of continual negotiation with disagreements and conflict which may lead some jurors to become anxious or angry: it may be that the issues become personal, even insulting; some individuals may refuse to revise their opinion; some jurors may even refuse to participate, sitting apart from the others, and subgroups may form within the larger group. The jurors' deliberations may be influenced, particularly in long trials, by resentments such as seeing the defendant as responsible for interfering in their everyday lives. Further, while sentencing is not the concern of the jury, jurors may reach a verdict on the basis of what will happen if they return a guilty verdict.

The process of jury deliberation is clearly important and, indeed, the research suggests that almost one-third of jurors do change their views during discussions. However, the best predictor of the juries' eventual verdict is the balance of opinion among jurors at the onset of their deliberations.

It is impossible to know how often juries make wrong decisions: it is likely that innocent men and women have been sentenced because of a wrong jury decision; it is equally likely that guilty people have been set free. A comparison of the judge's views with the jury verdict offers an insight into the frequency with which jurors reach a verdict that is, at least, at odds with an expert opinion. American research has compared the convictions and acquittals of judges and juries, finding that in more than 3500 trials, the judge and jury agreed in 78% of cases. When they disagreed, the jury acquitted in 19% of cases when the judge would have convicted, leaving only 3% of cases in which the judge would have acquitted but the jury found guilty. English research has reported similar findings: most of the time judges and juries agreed and in instances of disagreement the jury was more lenient. There are several possible reasons for juror leniency: a defendant with no history of offending may be given a greater benefit of doubt; the jury

may feel sympathy toward the defendant; or, in some celebrated cases, the jury disagreed with the law. Of course, to follow the point made above, the jury may reach an incorrect decision because of a failure to comprehend the high standard of proof needed to reach a decision or because of a lack of understanding of the evidence or the judge's instructions.

The Strength of the Research

A body of research evidence has accumulated that is relevant to the psychology of evidence. However, a great deal of this research, perhaps particularly in the area of eyewitness memory, has been carried out in laboratory settings. Laboratory-based research has obvious advantages for the researcher: it allows the investigator to control what the observer sees; it allows the investigator to select observers, say by age or sex; and it allows control of how the process of recall and recognition is structured. Indeed, the issue of control is central to laboratory research: by controlling as many variables as possible, the investigator can discover, with a high degree of confidence, the effects of the particular variables of direct interest. For example, in laboratory settings, observers generally recall violent incidents less accurately than nonviolent incidents. The key issue is therefore the *generalizability* of the findings: that is, to what degree does the laboratory-based research inform understanding of real-life cases? Critics of experimental studies have pointed to the limitations of laboratory studies – such as the use of staged crimes and filmed sequences and observer awareness of the focus of the research – as a means by which to understand the complexities of the task facing a real eyewitness. The limitations of laboratory research are such as to minimize the realism of the research and hence their applicability to real life. This point may be followed by questioning the professional wisdom of psychologists acting as expert witnesses and presenting such findings in real cases. Indeed, a field study by John Yuille and his colleagues considered a real-life case in which 13 of 21 witnesses to a shooting incident were reinterviewed 4–5 months after the event. The performance of the witnesses varied in a number of ways from what would have been predicted from the laboratory research, particularly with respect to the effects of violence on memory.

Should the findings from laboratory-based studies be disregarded in favor of field studies? The problem is that field studies are open to criticism on the grounds that are the very strength of laboratory research: that is, the sacrifice of control in the field setting. In the field study noted above, it is not known to what extent witnesses conferred with each other, how accurate the missing witnesses would be, and whether media coverage had any influence on what witnesses had to say when reinterviewed.

Is there a solution to this apparent impasse? While it is unlikely that two positions can be fully reconciled, there are two steps that can be made. First, with regard to the extant research, it is evident that not all the factors studied have an equal strength with respect to their relationship with the accuracy of eyewitness memory. Three categories of research findings have been defined: (1) reliable and strong factors that show consistent effects on eyewitness memory; (2) reliable and moderate factors that show effects in some studies but

not in others; (3) weak or noninfluential factors that have little or no effect on witness accuracy. In real-life cases, the psychologist acting as an expert witness may wish to refine their expert testimony to emphasize strong rather than weak factors. Second, looking to research design, the optimum approach is to gather data using a variety of research methodologies, including laboratory studies, case studies, field studies, and archival studies. Studies that are able to use a range of methodologies and produce consistent findings will considerably reduce the, quite proper, reservations about the applicability of research.

Conclusion

The historical emphasis in much of the psychological research has been to illuminate the fallibility of human performance, so alerting the criminal justice system to the potential for error. However, psychologists have also turned to the more constructive task of considering ways to aid the gathering of evidence. In particular, psychologists are studying ways of enhancing the quality of witness testimony through the use of more sophisticated interviewing procedures. The 'cognitive interview,' which uses memory-retrieval mnemonics to enhance recall, is one aspect of the developing field of investigative interviewing. For the future, forensic psychologists seem set to give increasing attention to the development and refinement of constructive approaches in applying psychology to the complex process of gathering evidence.

Serial Murder

According to the Federal Bureau of Investigation (FBI), serial murder is defined as *the unlawful killing of two or more victims by the same offender(s), in separate events*. These murders may occur over a period of days, weeks, months, or even years. This is in contrast to mass murder where, according to the FBI, four or more persons are killed at one time. In the United States, mass murders occur approximately every 10–14 days, which include both public killings and domestic mass killings. Serial murder, however, is usually not as noticeable at the outset but becomes more visible to the public as news of bodies being found are reported by the media.

Serial murder has been documented in the United States since the early 1800s. However, the incidence and prevalence of serial murder as a specific type of homicide did not come to public awareness until the late 1970s and early 1980s, when Robert Ressler, an FBI agent, was collecting data on multiple murders. Although not a scientific researcher, Ressler was a passionate investigator with a belief that he was amassing data related to cases of murder that were linked with distinct patterns of killing. Serial murder is a relatively rare phenomenon in comparison to other forms of homicide. On average, American serial killers have 10–13 victims that account for 250–400 victims per year in a country with over 300 million residents. The fact that many are sexual predators who often kill strangers such as prostitutes, college students, children, or the elderly generates fear in any community, regardless of the frequency. To fuel the fear and intrigue of such cases, many of these killers are given monikers such as the Boston Strangler, The 44. Caliber Killer, Angel of Death, Night Stalker, and Killer Clown.

In 1984, spurred by several highly publicized cases of serial murder, the FBI petitioned the US Senate for funds to establish the Violent Criminal Apprehension Program (VICAP). By the mid-1980s, the FBI had established VICAP at its Behavioral Science Unit in Quantico, Virginia. Currently, the program is designed to collect detailed information on homicides from cities throughout the United States. Investigators such as former FBI agents Robert Ressler, John Douglas, and Roy Hazelwood, all pioneers in the investigation and classification of serial killers and sexual predators, interviewed sundry infamous serial killers who sexually preyed upon prostitutes, female college students, and elderly women. Ressler and colleagues published their findings in *Sexual Homicide* (1988), which for many years was a standard reference text for this form of multiple murders. In addition, the US government continues to develop programs such as the National Center for the Analysis of Violent Crime to focus specifically on repetitive offenders, including serial murderers.

Myths of Serial Murders

Many myths, fueled by mass media, surround the phenomenon of serial murders including that the killers are intelligent, insane White males who are lust killers with dozens of victims. They act alone as they travel across the United States stabbing, strangling, and beating young women to death. Sexually abused as children, these defective predators cannot stop killing even if they want to and secretly hope that someone will catch them. The reality is quite different. Approximately 20% of offenders are African American. Between the years 2004 and 2011, approximately 51% of all American serial killers were African Americans. When male offenders who kill alone are considered, the number rises to 56%. This dramatic change can be attributed to the redefining of serial murder by the FBI as involving two or more victims. Of all serial killers, 16% are female and only 2–4% are legally insane. Some cases of serial murder are far more instrumental (i.e., killing for money) than expressive (i.e., killing for sexual purposes); most kill under 10 victims; 25% have one or more accomplices; and some, especially women, use poisons and/or guns to kill. Most serial offenders are of average intelligence, stay in a local area to commit their murder series, and are not trying to be apprehended. Some killers take months or years before they kill again and are very much in control of when and where they will kill. Others can be extremely impulsive and kill spontaneously. Although some offenders have been sexually abused, far more are found with histories of severe neglect, abandonment, and rejection by significant others.

Consider the following real cases of American serial murderers in the United States, many of whom do not fit the typical stereotypes purported by the media and immortalized by Hollywood:

- A hospital orderly suffocates over 50 male patients.
- A married woman kills five of her babies at birth and hides them in a closet.
- Two Black men randomly shoot and kill several people over a period of several months.
- An abortion doctor who catered to minorities, immigrants, and poor women, was charged with eight counts of murder in the deaths of a patient and seven babies who were born alive and then killed with scissors.
- A man who had been married for 25 years and held the same job for 30 years is also secretly a necrophile who is convicted of killing 48 prostitutes and then mutilating and having sex with the corpses, which he then buried in shallow graves.
- A White male stabs 20 men, most of them Black, as he travels across several states, killing five of them.

- A Native American who engages in civil war reenactments travels around the United States and kills 35+ White female college students.
- A nurse kills patients using prescription medications.
- Two elderly women befriend homeless men. After manipulating them into taking out life insurance policies and designating the women as beneficiaries, they care for the men for 2 years until the policies are in full force, then run them over with their car and collect the insurance money.
- A man lures female drug addicts and prostitutes to his home where he sexually assaults and murders 14 of them. The women were found buried in his back yard and in different places in his house.

An Operationalized Definition of Serial Murder and the San Antonio Symposium

In 2005, the FBI organized an international Symposium in San Antonio, Texas. Invited were 150 homicide investigators, forensic psychologists, forensic psychiatrists, and criminal psychologists. Their task was to define the phenomenon of serial murder in a uniform and cogent way that would dispel the various myths generated by the media. These myths continue despite data indicating that serial killers are neither all White males who kill for sex, nor all dysfunctional loners and compulsive killers who are insane or simply evil. The Symposium identified several primary motivations for serial murder including anger, criminal enterprise, financial gain, ideology, power, thrill, psychosis, and sex and concluded that no *single* identifiable cause or factor creates a serial killer. Multiple factors contribute to the development of serial murder, especially the offender's choice to engage in multiple homicides. These conclusions helped the members of the Symposium create an operationalized definition of serial murder. Specific factors were included in the new definition: each case must have one or more offenders and two or more murdered victims; they must occur in separate events at different times; and the time period between murders will separate serial murder from mass murder. As a result, a new definition of serial murder emerged: *the unlawful killing of two or more victims by the same offender(s), in separate events.*

Serial Murderers as Psychopaths

Most serial killers display an array of personality disorders and psychopathology, but very few are legally insane. Most people consider those who kill at will not to be of sound mind and therefore insane. However, psychopathology identifies persons such as serial killers who display a spectrum of issues related to an inability to emotionally attach to others, have little or no conscience, display little or no remorse, and are characterized by an indifference to the suffering of others. Other characteristics include glibness/superficial charm; a grandiose sense of self-worth/narcissism; pathological lying; conning, manipulative behavior; lack of remorse or guilt; shallow affect; callousness/lack of empathy; failure to accept responsibility for actions; need for stimulation/proneness to boredom; parasitic lifestyle; poor behavioral controls; early behavioral problems;

lack of realistic, long-term goals; impulsivity; irresponsibility; and criminal versatility.

Serial killers display these characteristics and many more, depending upon their level of psychological development. Consider serial killers to be on a continuum of pathological development. Many are of average intelligence, have long histories of criminal behavior, are impulsive and angry, fail to learn from their mistakes, and yet may have attachments to their mothers or other persons. Seldom do any serial killers have healthy attachments to their fathers, the reasons being divorce, abandonment, and rejection. When fathers are in the home, there is usually a history of violence, sexual abuse, neglect, and/or emotional estrangement.

The Trauma-Control Model outlines the cyclical nature of serial murderers developing at an early stage of life. Biologically, some persons are predisposed to violence and some predispositions can be exacerbated by childhood trauma. Once the cycle begins, the child develops feelings of inadequacy and low self-esteem that lead to fantasy development. Initially, these fantasies can serve as a refuge from physical and emotional abuse, but over time they evolve into fantasies of sexual acts, often violent. Most persons who experience childhood trauma find ways that are not violent to cope with these stressors. Serial killers develop a plethora of behaviors and fantasies that end in the suffering and death of others.

For some, childhood can be so traumatic that the child can experience psychological breaks with reality, or dissociation. For others, fantasies of control progress into violent fantasies that are often influenced by facilitators such as drugs, alcohol, obscene material, erotica, and pornography. Often these fantasies are sexualized, involving paraphilic behaviors that may include the suffering and sexual degradation of others. In serial murder, each homicide committed by the offender is followed by events that reinforce the desire/compulsion to kill. Usually, these events can be traced to loss, rejection, and/or abandonment.

Other serial killers are far more advanced in their psychopathology. They do not have long histories of criminal behavior or at least have avoided detection. They may be above average intelligence and have developed social skills that help them blend into their environment. They are social chameleons with an uncanny knack of blending into their surroundings. They are skilled at lying, manipulating others, and gratifying themselves. Psychopaths are generally viewed as aggressive, insensitive, charismatic, irresponsible, intelligent, dangerous, hedonistic, narcissistic, and antisocial. The foundation for the development of psychopathology is control and power over others. One of the hallmarks of real psychopaths is their lack of empathy (Figure 1).

Healthy persons generally are not interested in controlling others while psychopaths live to control others. Indeed, they need others to gratify their personal wants and needs. Psychopaths are perceived as exceptional manipulators capable of feigning emotions in order to carry out their personal agendas. Without remorse for the suffering of their victims, they are adept at rationalization, projection, and other psychological defense mechanisms. Although most serial killers are psychopaths or at least exhibit psychopathic characteristics, the majority of criminal psychopaths are nonviolent persons. Indeed, the majority of criminal psychopaths are white-collar

Figure 1 Hickey's trauma-control model for serial murder. (Predispositional factors and facilitators may or may not influence the serial killing process.)

criminals. They manipulate others for financial gain. Bernard Madoff is a good example of a white-collar psychopath. He displayed no propensity for killing, but had no problem creating a Ponzi scheme that bilked hundreds of people and organizations of over \$60 billion. In psychology, the term *semantic aphasia* is used to describe persons such as psychopaths who do not feel bad about harming other people. The expression 'they know the words to the song but do not feel the music,' is appropriate for psychopaths. Serial killers usually possess such psychopathic characteristics, which, in turn, help them in carrying out their murders.

Serial Murder Profiling Strategies

Considered for many years to be 'junk science' without credible scientific application, it was not until recently that profiling was vetted with scientific rigor. In retrospect, profiling in its infancy had little scientific merit. Indeed, neither the American Psychological Association nor its British counterpart has set forth specifications for psychological practitioners who engage in profiling. Some researchers today are still not convinced that profiling has scientific merit. Verde and Nurra posit that the practice of psychological profiling is in essence neither an inductive nor a deductive venture, but rather a process of abduction wherein one can only hope to generate particular possibilities between pieces of fact as opposed to the causal rules or exact results often contrived by fictitious profilers such as Sherlock Holmes. These researchers hold that the profiles generated from multiple abductions become increasingly less definitive and as such refer to the generation of psychological profiles as less of a scientific endeavor and more of an art.

Devery takes a more negative view of the utility of past and current profiling practices. He argues that a dearth of evidence exists in supporting the application of profiling. He states that no support can be found where profiles have been of notable merit in cracking cases of serial murder or rape. He further notes instances where profiles have proven inaccurate and suggests that profiles can actually hinder investigations and

even condemn the innocent. He concludes that if ever profiles are used, they should be done so with the utmost care. Others like Schlesinger see utility in profiling but argue that a profiler cannot hope to identify an offender and that profiles can be useful only in honing in on a particular type of offender.

Yet, several researchers find considerable utility in profiling cases of serial murder. Instances of serial murder have influenced the development of numerous approaches in profiling that identify salient factors such as psychosocial, behavioral, and physical characteristics of offenders, victims, crime scenes, and modus operandi (MO). Kocsis suggests that much of the empirical conjecture regarding criminal profiling is the result of what is described as the 'nomenclature illusion' in which the production of superfluous terms and distinctions leads to misperceptions that hinder the scientific examination of the practice of profiling. However, Alison et al. advocate increased classification of the various contributions that are encompassed under the heading of profiling. They support the utility of the term 'behavioral investigative advice' and suggest that this approach should encompass the practices of (1) suspect prioritization, (2) linking crimes and crime scenes, (3) geographic profiling, (4) the interviewing process, and (5) risk assessment of offenders in clinical settings.

Some of these forms of profiling techniques include

- *Offender-victim profiling* – Law enforcement agencies collect information, often gathered from previous investigations and formed into general descriptions of persons most likely to commit or be associated with certain types of criminal behavior as well as the psychosocial and behavioral characteristics of their victims. In similar recognition of the difficulty with which profiles are generated, Canter attempts to illustrate this artistic procedure through what he refers to as 'profiling equations.' He notes that in such nonmathematical linear equations, factual information gathered from the crime allows for inferences on the part of the profiler regarding attributes befitting the offender. According to Canter, these inferences can result in the identification of several conclusions concerning the offender and the manner in

which he/she offends that are meant to aid criminal investigations; for example, in examining the behavioral changes exhibited by serial murderers across their first, second, and third homicides.

Sorochinski and Salfati discovered that offenders likely experiment with the manner in which they carry out their crimes. They differentiated planning behaviors into pre/post designations, wounding behaviors as having either a goal or process orientation, and offender–victim behaviors as separated by the victim being viewed by the offender as a ‘vehicle’ or as an ‘object.’ They noted that the highest degree of variation appeared in the commission of the second offense, a finding they found as being consistent with prior research in its indication of attempts at experimentation on the part of the offenders. Wounding behaviors were found to be the most varied of the classifications. The lesser degree of variation found in the styles of interaction between offender and victim may provide useful information to profilers.

- *Equivocal death profiling* – Also referred to as *psychological autopsy*, investigators gather and use information to explain personal motivations of a person(s) engaged in suicide pacts or deaths where motivations and/or reasons are difficult to determine.
- *Psychological profiling* – Investigators examine crime scene evidence to determine personality types of those committing the crimes. The purpose is to provide direction to investigators as they develop leads in cases.
- *Crime scene profiling (or criminal investigation analysis)* – It originates from the FBI model at the Behavioral Science Unit. Investigators evaluate descriptions of crime scenes, physical evidence, and criminal behavior before, during, and after the criminal activity, including victim data.
- *DNA profiling* – Murder cases are sometimes solved using improved techniques in DNA profiling or genetic science. This involves matching DNA from crime scenes to victims and offenders in efforts to identify perpetrators involved in specific crimes.
- *Geographical profiling* – Also known as *spatial mapping*, this approach combines geography and environmental criminology in connecting crime scenes to offender habitats and locations they use to prey upon victims.
- *Paraphilia profiling* – Criminal paraphilia, or sexual gratification using fantasy and/or illegal sexual activity, involves the identification of various forms of paraphilia used by sexual offenders or sexual predators. This involves understanding paraphilia and the role of *relational paraphilic attachment (RPA)* and how sex offenders attach themselves through fantasy and behavior with their victims. This may include the use of specific language, behaviors, physical objects, sounds, smells, voices, and many others that are particular to the offender such as the use of specific recording devices, ligatures, victims, photographs, and weapons that aid in fulfilling the fantasies of the offender(s).

Serial Murder Signatures and Paraphilia

Serial killers, especially those who are sexual predators, will have distinctive fantasy-driven behaviors that make the crime and the offender(s) unique. Many of these fantasy-driven behaviors are

rooted in paraphilia or the quest for sexual gratification through unusual acts and imagery. According to the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (*DSM-IV*), published by the American Psychiatric Association, many of the terms listed describe various forms of *paraphilia*. The *DSM-IV* describes three general classifications of paraphilia:

1. Preference for the use of a nonhuman object for sexual arousal.
2. Repetitive sexual activity with humans that involves real or simulated suffering or humiliation.
3. Repetitive sexual activity with nonconsenting partners.

There are many documented paraphilia, some more common than others. These include fetishes, voyeurism, exhibitionism, frotteurism, sadomasochism, animal torture, necrophilia, pedophilia, and many others. Serial killers who are sexual predators experiment with a variety of paraphilia starting with less intrusive forms such as voyeurism and exhibitionism to more aggressive forms such as lust murder, pyromania, and necrosadistic murders. The following ‘attack’ paraphilia are common to sexual predators who commit serial murder:

- Amokoscisia – arousal or sexual frenzy with desire to slash or mutilate women
- Anophelorstia – arousal from defiling or ravaging a partner
- Anthropophagolagnia – rape with cannibalism
- Biastophilia – those preferring to violently rape their victims; also called raptophilia
- Dippoldism – sexual arousal from abusing children
- Necrophilia – sex acts with corpses
- Sadism – empowerment and arousal derived from injuring others; often associated with other attack paraphilia

Crime scenes created by sexual predators who become serial killers usually leave *signatures* or personal expressions or markings of the offender that reflect fantasy development. These may include verbal and/or physical acts. Sometimes referred to as *calling cards* or *trademarks*, the signature is not required to commit the crime but rather to fulfill the fantasy of the killer. Sometimes the MO used by the killer to commit his murders becomes part of his signature. For example, sexual predators who are serial killers develop a pattern of stalking behaviors that may be sexualized as the behaviors are carried out. Cary Stayner, the Yosemite Park killer, murdered some of his victims by decapitating them. In this case, the method of killing was also an expression of his paraphilic fantasies, including forested locations where he preferred to kill his victims. Thus, his method of killing provided him sexual gratification and in turn his MO became his signature. These signatures, or *paraphilic footprints*, are extensions of an offender’s RPA to his victim and aid the offender in actualizing his fantasies.

Stalking

JR Meloy, University of California, San Diego, CA, USA

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Attachment A psychobiologically based behavioral system which is present in humans from birth and is evident in seeking physical closeness to the love object. In infancy this is the mother; in adulthood it is often the sexually intimate partner.

Envy The wish to damage or destroy the goodness in another.

Jealousy Competitive feelings for the love object.

Obsession Repetitive, frequent thoughts which may impair the daily functioning of the person; when extreme, they are called fixations or pathological preoccupations.

Psychosis A generic term for a loss of contact with consensual reality and the creation of a private, bizarre, idiosyncratic reality; may be caused by a variety of mental disorders.

Validation To scientifically demonstrate the usefulness of a measure.

The crime of stalking contains three elements: a pattern of unwanted following or harassment; a credible threat; and the induction or intent to induce fear in the victim. Without victim awareness, there is no crime of stalking. This eliminates the inappropriate application of the term 'stalking' to describe violent crimes in which some form of surveillance precedes an attack, such as rape or robbery. Unwanted pursuit and sustained fear are the *sine qua non* of stalking.

Large-scale representative studies of stalking across three continents indicate that 2–13% of males and 8–32% of females will be victimized by a stalker at some point in their adult lives. These figures encompass clinical, forensic, general population, and college samples. Females are the target in 80% of the cases, and almost half of all stalking cases involve a prior sexual intimate as the perpetrator. The average duration of stalking is 2 years, but in one large study the modal duration was 1 month. Most stalkers have known their victim in some capacity before the stalking begins. Unfortunately, stalking is a crime that has only received attention in Westernized developed countries, although other areas of the world are beginning to take notice.

The two most validated typologies of stalkers focus upon clinical and operational concerns. The clinical typology was developed by Mullen et al. at the Victorian Institute of Forensic Mental Health in Melbourne, Australia, and consists of five groups: the rejected, the resentful, the socially incompetent, the intimacy seeking, and the sexually predatory. There is a growing body of work which utilizes this typology for treatment and management of both stalkers and their victims.

The operational typology of stalking is called RECON (relationship and context), and identifies four groups of stalkers: those who target prior intimates, prior acquaintances, public figures, and private strangers. This typology was developed utilizing a large nonrandom sample of stalkers ($N=1005$) in North America, and showed good interrater reliability and discriminant validity. It was created for use by law enforcement and security professionals. Both typologies show equivalency in the prediction of violence risk.

Stalking behavior predictably includes a number of tactics:

1. Hyperintimacy – rapidly trying to accelerate intimacy which induces fear or anxiety in the victim

2. Proximity/surveillance – watching or following the victim
3. Invasion – violating the privacy of the victim
4. Proxy pursuit – using third parties to follow the victim
5. Intimidation or harassment – threatening or psychologically manipulating the victim
6. Coercion/constraint – forcefully restricting the behavior of the victim
7. Aggression – being violent toward self, the victim, third parties, or property

One third of stalkers will be physically violent toward their victim during the course of their pursuit. The frequency of violence substantially increases when the stalker is a prior sexual intimate of the victim, and exceeds 50%. This is a highly replicated finding, and suggests that sexual intimacy intensifies attraction, attachment, and emotional reactivity when a bond is threatened.

The nature of the violence in such cases is usually *affective*, characterized by heightened autonomic arousal, anger or fear, the presence of a threat (usually fear of abandonment), and a lack of planning. It is impulsive, reactive, and immediate. Such violence contrasts with the nature of violence when a public figure is stalked and attacked, which is usually *predatory*: planned, purposeful, and emotionless. These two modes of violence are psychobiologically distinctive in mammals, including humans. Risk of homicide in all stalking cases involving prior sexual intimates is estimated to be 0.25%, and data suggest that stalking is a risk factor in the prediction of spousal homicide.

The earlier prediction of violence research found a number of variables that were significantly related to stalking violence, including the presence of threats, substance abuse, a prior sexually intimate relationship, personality disorder, a history of violent behavior, and the absence of psychosis. One study in the prediction of stalking violence utilized a regression tree approach which generated subgroups that have different probability estimates of violence through the interaction effects of the predictor variables. The most useful model contained nine variables: age under 30 years, education less than high school, threats toward the victim, prior intimate relationship, revenge motivation, psychotic disorder, personality disorder, substance

abuse history, and criminal history. The directionality of some of these variables depended on their interaction with other variables. Such sophisticated models may pave the way for actuarial software programs which will fairly accurately assess risk of violence over a particular period of time.

Other advanced work in stalking risk assessment focuses upon efforts to predict physical violence and persistence in stalking cases. Models have been developed which elucidate the predictor variables for the various subtypes of stalkers according to the Mullen et al. typology. Violence risk assessment of a particular subject is most useful when the evaluator initially focuses on status (distal or static) variables, such as age <30 and prior violence, and then turns to state (proximal or dynamic) variables, such as threats, proximity seeking, and current drug use, which individualizes the approach. There are two structured professional judgment instruments to assess violence risk in stalking cases: *The Stalking Risk Profile* and *Guidelines for Stalking Assessment and Management*. Both tools are based upon extant empirical research and the clinical work of the authors.

The paradox of stalking – an individual is pursued that is continuously rejecting – is best understood as a pathology of attachment. Attachment is a biologically rooted, species-specific behavioral system that is either secure or insecure, and in cases of stalking, the attachment pathology is insecure and often *preoccupied*. Numerous studies have tested and confirmed this hypothesis first proposed by Meloy. Kienlen first found in a small sample of imprisoned stalkers that the majority had lost a primary caretaker in childhood and had also suffered a major loss within a year prior to the onset of stalking. These two findings suggest both predisposing and precipitating events that may contribute to the onset of stalking. Stalkers typically remember their parents as emotionally neglectful and have insecure attachment styles.

Adult stalkers are usually males in their fourth decade of life with prior psychiatric, drug abuse, and criminal histories. They often have both a major mental illness and a personality disorder, necessitating a psychiatric and psychological evaluation to discern the best approach to treatment and risk management. Psychosis occurs in a minority of stalkers, but is more likely among stalkers of strangers and/or public figures. Questions remain concerning the psychopathology of college students who engage in 'obsessive relational intrusion,' a sub-criminal form of stalking.

Stalkers are preoccupied with thoughts of their object of pursuit. If an obsession is functionally defined as an abnormal frequency of preoccupation with an object, substantial data indicate that obsessional thinking is the most common cognitive trait of the stalker. The content of the stalker's conscious thoughts varies from case to case, but thinking is generally characterized by paradox and contradiction. Examples include the juxtaposition of statements that both idealize and devalue the victim; the wish for complete freedom for the victim alongside demands for complete control; or statements of rage commingled with yearnings for love and affection.

The preoccupations and contradictions which characterize the stalker's thinking may be unconsciously rooted in 'narcissistic linking fantasies,' recurrent thoughts of a special and unique relationship with the love object. Such fantasies are normal in the initial stages of romance or infatuation, yet in the case of stalking, they are met with rejection when acted

upon, and they usher in emotions of intense humiliation and rage that the stalker will express toward the victim. In normal men and women, romantic rejection often triggers feelings of grief, anger, and sadness, and the search for a new love object. When pathological narcissism predominates, such as one sees among stalkers, the intensity of their fury is a measure of their degree of ego deflation and may accelerate their pursuit.

The two most prominent emotions among stalkers are anger and jealousy. Such feelings are often consciously felt and acknowledged by the stalker, but often defend against other more vulnerable feelings and deficiencies outside his awareness, such as shame, loneliness, isolation, and social inadequacy. Anger often fuels the pursuit of the victim, and may be further motivated by envy to damage or destroy that which cannot be possessed, or a wish to inflict pain upon the one who has inflicted pain, the primitive impulse of *lex talionis*, an eye for an eye. Anger can also repair narcissistic wounds through a fantasized sense of omnipotent control over the victim. Victim surveys have noted that the most common perceived motivation of the stalker is a desire to control her.

Jealousy is a complex emotion, and is defined interpersonally as competition for the love of the object. Pathological or morbid jealousy may be apparent in some stalkers, and may reach delusional proportions, sometimes seen in cases of celebrity stalking. Jealousy also may motivate behavior to dominate and isolate the victim, and has predicted stalking in one study.

The psychological defenses used to manage such intense emotions include minimization, denial, projection of blame, and projective identification. Defenses serve to protect the stalker's inflated sense of self, but at a price. He remains vulnerable when confronted by his behavior, which paradoxically can escalate his rage. He inhabits an intrapsychic world populated by his own persecutory objects, but his fantasy of being persecuted can be confirmed by third parties, such as a husband, an attorney, or a police officer, who are trying to stop his incessant pursuit.

Although most stalkers are male, 15–20% are female. Female stalkers are less likely to have a history of violent criminality or substance abuse, and less likely to stalk a prior sexual intimate than male stalkers. They are more likely than male stalkers to pursue an acquaintance, and to pursue a victim of the same gender. Threat and assault rates, on average, are the same as men. In one large study of female stalkers, the women were in their 30s, single, educated, and intelligent. A minority were prior sexual intimates of the victims. Usually the victims were slightly older men who knew them as acquaintances. Unlike male stalkers, female stalkers appear to be motivated to *establish* intimacy with the victim, whereas their male counterparts are attempting to *maintain* intimacy with their victim. However, the more intimate the relationship had been prior to the stalking, the greater the risk of violence. The most common documented emotion among the women was anger, particularly abandonment rage. The most common personality diagnosis was borderline personality disorder. Although there are very few studies of female stalkers, recent work has largely confirmed these earlier findings.

Pathological narcissism appears to be less frequent among female stalkers, who are more intent on forming a relationship to assuage feelings of loneliness, dependency, and anger.

There are no randomized and controlled studies concerning the treatment of stalkers. The effectiveness of mental health interventions is currently based upon anecdotal data. There are efforts underway to measure treatment outcome in a comprehensive program in Victoria, Australia, and treatment and management recommendations are becoming more refined and focused. The importance of a correct diagnosis, which is often complex, and an accurate understanding of the stalker's motivation are recommended before treatment begins. Stalking motivated by major mental disorder is typically more treatable than stalking that is the result of personality disorder. The treatment of choice for the latter is long-term psychodynamic psychotherapy.

Victim impact in stalking cases is severe and chronic. More than one third of stalking victims will incur a psychiatric diagnosis that will persist long after the stalking has ceased. Many victims have their personal and professional lives seriously disrupted. Risk management of stalking cases is long term, difficult, and complex due to the reluctance of law enforcement to prosecute such behavior and the impressive tenacity and intelligence of some stalkers. Effective risk management encompasses many principles which have been elucidated elsewhere, but generally focuses upon four recommendations:

First, stalking victims often minimize or deny the crime being committed against them for weeks or months. It is imperative that any unwanted pursuit that induces fear should be recognized as a serious problem, if not a criminal activity, and be treated as such by contacting law enforcement. Some large urban areas have police units devoted to stalking.

Second, stalking victims often attempt to resolve the problem alone. It is imperative that professional help be sought, including contact with both law enforcement and mental health. Stalkers are typically psychiatrically impaired, and efforts to dissuade a stalker often involve simultaneous police and psychiatric interventions.

Third, stalking victims often destroy evidence. It is imperative that all evidence of unwanted pursuit, including notes, letters, e-mails, objects, gifts, audio and video recordings, text messages, and other means of communication be kept in a safe place for eventual prosecution. Stalking laws often require the establishment of a *continuity of purpose* by the stalker, and such evidence is critical in proving a case.

And fourth, stalking victims often decide to initiate contact with the stalker to reason with him. It is imperative that all direct contact with the stalker be avoided, especially contact initiated by the victim – although the stalker's ability to continue to communicate his thoughts to the victim should not be removed (e.g., e-mail address, telephone number) as a source of intelligence gathering concerning his state of mind. If the victim attempts to meet with the stalker, it will probably reinforce his behavior, and may increase his frequency of pursuit. One cannot reason with someone who is behaving unreasonably and in many cases dangerously.

Glossary

Electrophoresis Separation of macromolecules (i.e., DNA fragments under the influence of a spatially uniform electric field).

Genetic marker Observable trait that can be used to trace the presence of genes determining (or linked with) its variable forms.

Polymorphism Simultaneous occurrence in the same locality of two or more discontinuous forms in such proportions that the rarest of them cannot be maintained just by recurrent mutation or immigration.

The Early Times

Forensic genetics can be defined as the application of genetics (in the sense of a science with the purpose of studying inherited characteristics for the analysis of inter- and intraspecific variations in populations) to the resolution of legal conflicts.

The evolution of forensic genetics has been driven by analysis of human genetic variation, beginning over a century ago with Karl Landsteiner's discovery of the human ABO blood group variants (termed polymorphisms) and his early realization that this variation was applicable in solving paternity testing cases and crimes.

During the first half of the twentieth century, different polymorphic human red cell antigens were discovered, although the application of forensic genetics to criminal casework was rather limited due to the difficulties of analyzing minute bloodstains and body fluids other than blood. In addition to the ABO system, there were about 15 other well-established blood groups with potential for forensic serology, including the MNS system, and the Kell, Duffy, Kidd, and Lutheran systems were among the most widely used in forensics.

The characterization of human variation in immunoglobulins, especially the discovery of polymorphic proteins and enzymes in serum and red blood cells, represented a significant advance in this field particularly for paternity testing.

Since the discovery of the first serum protein polymorphism in 1956, the number of polymorphic proteins that can be analyzed by electrophoretic methods continuously increased up to the late 1970s. Haptoglobins, the group-specific component, transferrin, alpha-1-antitrypsin, orosomucoid (some complement factors C3, C4, C6, C8, and Bf), coagulation factors (FXIII and ATIII), plasminogen, amylases (AMY1 and AMY2), and immunoglobulin markers were the most used.

The same occurred with red cell and leukocyte polymorphic enzymes, most of them discovered in the 1960s and 1970s. The more widely used were phosphoglucosmutase-1, erythrocyte acid phosphatase, esterase D, adenylate kinase, glyoxalase, adenosine desaminase, glutamate-pyruvate transaminase, uridine monophosphate kinase, peptidase A, and 6-phosphogluconate dehydrogenase.

MHC class I loci were introduced in 1962, 4 years after the original description by Jean Dausset of the first antigen on lymphocytes, when van Rood defined the first two alleles at what is now known as the HLA-B locus.

HLAs were more polymorphic than any other genetic markers used up to that moment and represented an important improvement in paternity testing despite the fact that the methodology used (based on a microlymphocytotoxicity method first described by Terasaky in 1964) had some interpretation difficulties due, in part, to the cross-reactivity of some antigens and the complexity of statistical interpretation due to linkage disequilibrium within the main HLA loci.

While studying the HLA-A and B locus antigens, it was observed that some exceptions could not be reconciled with the two-gene model and with the use of a special technique called 'capping' (antibody-mediated antigen aggregation on the cell surface), the existence of a third locus, HLA-C, was

demonstrated. HLA-A, B, and C were widely used in paternity testing labs; at the beginning of the 1980s some groups using monoclonal antibodies, enzyme-linked immune absorbent assays, and isoelectric focusing started to report some success in the analysis of HLA in fresh bloodstains.

The use of these classical genetic markers was nevertheless limited when it was necessary to analyze minimal or degraded material, which is commonly encountered in forensic cases. In addition, it was difficult to analyze biological material other than blood, and therefore the information obtained from hair, saliva, and even semen in rape cases was rather limited.

Electrophoretic techniques were preferred over immunological procedures due to the interpretation of results being more objective and to the fact that the polymorphic proteins and enzymes had low variant frequencies, making it necessary to obtain as much information as possible. For this reason, sophisticated electrophoretic methods such as isoelectric focusing, immobilized pH gradients, or hybrid isoelectric focusing were developed and applied. The introduction of silver-staining methodologies on polyacrylamide gels increased the sensitivity of detection and therefore the possibility of analyzing polymorphic proteins in minute bloodstains.

In spite of this, the information that forensic geneticists were able to report in many cases was clearly insufficient and, therefore, the discovery of hypervariable loci in minisatellites by Jeffreys et al. represented a milestone in the field and one of the most important discoveries in the history of forensic science.

DNA Typing: Minisatellites and Short Tandem Repeats

DNA typing provided evident advantages over traditional protein analysis, principally because it is more informative and can be analyzed in minute or degraded material since DNA is physically much more resistant to degradation than proteins. In addition, the same DNA genotype can be obtained from any tissue (i.e., blood, saliva, semen, hair, skin, and bones), whereas the analysis of protein markers is restricted to cells where these proteins are expressed.

Minisatellites were initially detected by hybridization of probes to Southern blots of restriction-enzyme-digested genomic DNA, and shared 'core sequences' between different minisatellite loci allowed probes to be applied to detect many independent minisatellites simultaneously, yielding the hypervariable multiband patterns known as DNA fingerprints.

Originally, multilocus probes were proposed for forensic genetic analysis. However, these types of probes were not very successful in the forensic field, because although highly informative, statistical problems of evaluation of the evidence in cases of band matching and standardization arose. For these reasons, multilocus probes were substituted in the forensic field by the use of specific cloned minisatellites, 'single locus probes' (SLPs), where each revealed only a single, highly polymorphic, restriction fragment length polymorphism, thus simplifying interpretation. Typically, four SLPs were used successively to probe a Southern blot, yielding eight hypervariable fragments per individual.

It was with SLPs that the first DNA-based criminal investigation was carried out; this case culminated in the conviction of Colin Pitchfork for a double rape and homicide in Leicestershire in 1986. Very soon, DNA analysis became the standard method in forensic genetics as it was used by the majority of laboratories in the full range of applications, especially in criminal forensic casework (stain analysis and hairs) and identification.

Until the introduction of short tandem repeat (STR) analysis by polymerase chain reaction (PCR) amplification, the analysis of minisatellites with SLPs was very popular in forensic laboratories.

The main advantage of SLP analysis is the enormous variability of some of the minisatellite loci and well-documented knowledge of the mutation rate in some of them. The main disadvantages are the time needed for the analysis and the need for relatively large amounts of nondegraded DNA required for successful SLP typing. Since DNA extracted from forensic specimens is often degraded due to environmental conditions, SLP techniques have often failed to produce reliable results. The PCR has overcome these difficulties and it has strongly enhanced the usefulness of DNA profiling techniques in forensic science.

The PCR method was devised and named by Mullis and colleagues at the Cetus Corporation in 1987, although the principle had been described in detail by Khorana et al. over a decade earlier; however, the use of PCR was limited until suitable heat-stable DNA polymerases became available from thermophilic bacteria.

Most PCR-based DNA typing systems allow alleles to be identified as discrete entities, thereby making standardization easier by avoiding most of the statistical issues that arise in matching and binning SLP bands that occupy a continuum. Additionally, apart from the increased sensitivity inherent in any PCR technique, it is more likely to be successful in analyzing old or very degraded material mainly because of the smaller size of many of the DNA polymorphisms (SNPs and STRs), making them more amenable to analysis by PCR.

The first group of markers used after PCR amplification were HLA-class II genes, especially the HLA DQA1 system analyzed with the use of sequence-specific oligonucleotide probes. Almost immediately after it was shown to be feasible to analyze DNA markers by PCR technology, kits became commercially available for several genetic loci. The AmpliType PolyMarker PCR amplification kit (Perkin-Elmer, Foster City, CA, USA) was very popular in forensic labs at that time. With this kit, the loci HLA DQA1, LDLR, GYPA, HBGG, D7S8, and GC are amplified in a multiplex fashion. The last five loci listed were typed simultaneously in a single reverse dot-blot strip containing ASO probes; HLA DQA1 was typed in a separate strip.

The efforts of forensic scientists were then addressed to the amplification of fragment length polymorphisms. The minisatellite D1S80 (pMCT118) was the first one to be applied to forensic analysis but all these early PCR systems were superseded by STRs (alternatively termed microsatellites). Analysis of STRs by PCR is now the method of choice for DNA-based forensic identification.

STRs were discovered in 1989 and were applied to forensic cases at the beginning of the 1990s. The advantages of using tetra- and pentanucleotide repeat STRs (4- and 5-base repeat units) over di- and trinucleotides (2- and 3-base repeats) soon became apparent and a systematic search for the most

convenient STRs started. This was followed by the process of standardization of techniques and nomenclature accomplished by bodies such as SWGDAM in the United States and EDNAP in Europe plus the active role of the DNA Commission of the ISFG.

Another important step was the possibility of amplifying multiple STR loci in a single combined multiplex PCR reaction. When this PCR approach was coupled with direct detection of amplified products in polyacrylamide gels, STR DNA profiling became amenable to automation. Commercial STR multiplexes for manual electrophoretic systems were available from 1993. Denaturing polyacrylamide gels were used for the separation of DNA fragments until the introduction of capillary electrophoresis that, together with the introduction of fluorescent-based dye-labeled primer technology and the use of DNA sequencers, revolutionized the field, allowing the typing of large STR multiplexes. Several commercial dye-labeled multiplexes have since become available and all include a range of STRs plus amelogenin for sex determination. The currently used multiplexes combine 15 STRs or more. The combined discrimination power of STRs is very high and the probabilities of two unrelated individuals matching by chance (random match probability – RMP) are lower than 10^{-15} for most of the larger STR multiplexes.

Since the mid-1990s, computer databases containing STR profiles from crime scene samples, convicted offenders, and, in some cases, persons arrested but subsequently cleared of a crime have provided law enforcement agencies with the ability to link offenders to crime scene STR profiles. Application of this technology has enabled thousands of crimes to be solved around the world.

Finally, the redesign of PCR primers, which were closer to the STR repeat region, enabled in 2001 the creation of 'miniSTRs' with potential for improving analysis of degraded biological material.

Polymorphisms in Sexual Chromosomes and Mitochondrial DNA

Y-chromosome-specific polymorphisms have proved to be especially useful in forensic analysis and have been used since 1995. The applications of Y-chromosome polymorphisms include analysis of deficiency paternity testing of a male offspring (e.g., mother unavailable for testing) and different applications in criminal casework. Y polymorphisms are particularly interesting for the analysis of the male DNA fraction in stains involving male/female mixtures, the most common biological material available from the analysis of sexual crimes.

In the same way as autosomal STRs have risen in number, Y-STR marker sets have expanded and commercial multiplexes now offer an analysis of Y-STRs to create a useful haplotype. As uniparental loci, passed on in the parental lineage from male to male, statistical interpretation in cases of a Y-STR match is more complicated and appropriate corrections must be made taking into account population substructure and sampling errors. Population surveys are therefore very important and quality-controlled population databases have been compiled by developing a global database organized as the Y-chromosome haplotype reference database. At the same time as Y-STRs, STRs in the X-chromosome were also introduced and these

Figure 1 Genetic markers used in forensic genetics.

markers are of interest for some deficiency parentage testing cases.

During the time STR typing was beginning to utilize fluorescent labeling in the early to mid-1990s, mitochondrial DNA (mtDNA) was introduced for forensic applications. Analysis of the mtDNA control region, a segment of the whole mitochondrial genome, is an efficient method for the study and comparison of bones, old and degraded DNA, and, especially, the analysis of telogenic hairs. In these cases, samples of mtDNA variation can be analyzed using a variety of strategies. The combination of PCR amplification with direct DNA sequencing is usually the optimum approach for identification and it has proved to be a reliable and reproducible method in forensic casework, used in forensic laboratories since the mid-1990s (Figure 1).

Single-Nucleotide Polymorphisms and the Technological Revolution

The last few years have been very exciting in the field of forensic genetics. First, a new type of marker has been introduced: single-nucleotide polymorphisms (SNPs). SNPs have a number of characteristics that make them very appropriate for forensic studies. First, they have lower mutation rates than STRs and this is valuable for paternity testing. Second, they can be analyzed in short amplicons and, in general, short sizes are desirable since the size of the amplified product is critical for the successful amplification of degraded samples. Finally, they are very suitable for analysis using high-throughput technologies and the use of high-density SNP microarrays has recently been successfully implemented for the identification of very distant relationship investigations in incomplete pedigrees. A variety of SNP panels for different forensic applications have been proposed and validated. Similarly, insertion-deletion polymorphisms or indels have proved to be especially valuable since they are simple, robust, and easy to analyze and interpret.

Ancestry-informative marker SNPs with marked allele frequency differences in populations have been found to be particularly useful to predict the geographic origin of individuals from biological material and have been successfully used in important forensic cases such as the analysis of unmatched

STR profiles in the investigation of the 11-M Madrid terrorist attack.

SNPs for the prediction of physical traits are being discovered and are likely to prove particularly useful to predict aspects of common phenotype variation such as eye color.

Nonhuman species in forensic genetics is an emerging field with a promising future. Forensic analysis of animal DNA has been used both when animal material (usually pet hairs) is found at crime scenes and in investigations of the illegal trade in endangered species. As with animal material, plant material can be associated with a crime scene and provide vital evidence. The same is true for analysis of bacterial strains in soil through new metagenomic approaches.

One of the most difficult problems facing the forensic biologist is the identification of body fluids. Molecular biological approaches to the identification of blood, semen, and saliva stains using analysis of specific mRNAs (which are surprisingly stable) have been described, and are likely to increase in use and importance.

New-generation sequencing technologies are also going to have an impact on many of these new applications.

Despite all these technical advances, the single most important advance in forensic genetic thinking is the realization that the scientist should address the probability of the evidence. It remains the case that statistics is still the one area of forensic genetics with more challenges in the field.

Forensic genetics is nowadays a well-established discipline with a defined body of knowledge, university chairs with this denomination, scientific societies, and specific devoted journals.

Glossary

Allele Each of the alternative forms of materializing the genetic information at a locus.

Codominance The relationship between alleles (symbolized by A1 and A2) that phenotypically allows the distinction between all genotypes involving any pairwise combination of them.

Dominance An allele (symbolized as A) is said to be dominant relatively to another one (recessive, symbolized by a) if the homozygous AA are phenotypically indistinguishable from the heterozygous Aa.

Gene Synonym of locus or allele, depending on context.

Genetic marker Observable trait that can be used to trace the presence of genes determining (or linked with) its variable forms.

Genotype Each of the classes into which the individuals of a population can be grouped according to the allelic state of the locus under study. For example, in homozygosity, the locus is occupied by a pair of identical alleles, whereas in heterozygosity, two different alleles occupy the same locus.

Hardy-Weinberg principle The generalization of Mendelian theory to population level. Assuming panmixia (random matings, infinite population size) and absence of mutation, selection, and migration, the following relation between allelic and genotype frequencies is expected: $(\sum \text{gene frequencies})^2 = \sum \text{genotype frequencies}$. For instance, if p and q stand for the allele frequencies (A and a) at a locus; then

	A	a
	p	q
A	AA	Aa
p	p ²	pq
a	Aa	aa
q	qp	q ²

Heterozygosity See *Genotype*.

Homozygosity See *Genotype*.

Locus (plural: loci) Level of genetic information corresponding to a Mendelian characteristic.

Mendelian characteristic Observation unit that presents a discontinuous distribution (the individuals appear grouped into classes) in the population under study and for which a simple mode of transmission can be established.

Mendelian chessboard Algorithm used to facilitate the prediction, in probability, of the genetic structures of the offspring, knowing the genotypes of the parents. For example, to predict the genetic structure of the offspring from the Aa × Aa mating type:

		Types of gametes	
		A	a
Types of gametes	A	AA	Aa
	1/2	1/4	1/4
	a	aA	aa
	1/2	1/4	1/4

Expected genotype proportions: 1/4 AA; 1/2 Aa; 1/4 aa (or 1:2:1). Expected phenotype proportions: 3/4 A; 1/4 a (or 3:1).

Mendelian theory of heredity (applied to the study of the homogametic transmission of one characteristic) For each Mendelian characteristic, two alleles exist per locus per individual (one of maternal origin, another paternal); in each gamete, only one is present, the choice being random (i.e., for a heterozygous individual, the probability of each type of gamete is 1/2).

Phenotype Each of the classes into which the individuals of a population can be grouped according to a Mendelian characteristic.

Recessivity See *Dominance*.

Definition

According to the official journal (*Forensic Science International: Genetics*) of one of the leading international scientific societies devoted to this field, forensic genetics can be defined as: 'The application of genetics to human and nonhuman material (in the sense of a science with the purpose of studying inherited characteristics for the analysis of inter- and

intraspecific variations in populations) for the resolution of legal conflicts.' Many other sciences have been applied to forensics, but forensic genetics possesses a profoundly different epistemological status among all other sister disciplines. Indeed, traditional forensic sciences rely upon a central assumption: the principle of discernible uniqueness. Under this principle, if two marks are indistinguishable, they must have been produced by the same agent, and conversely, markings

produced by different agents should be observably different and, therefore, when a pair of markings is not observably different, the conclusion is that they were made by the same agent. Genetics proceeds in the opposite way; it does not rely on the uniqueness assumption, and in contrast, it deals with *types* of observations that are not individually unique – in fact, they are indistinguishable among all members of the same observational class.

The full comprehension of these differences requires a brief overview of the genetic theory, which will be the next section's theme, but it is possible to entertain a brief comparative analysis of the two contrasting approaches. In classical fingerprints (or bullets, photos, etc.), expert comparisons employ a wide range of techniques, and a set of measurements is obtained. These data, along with visual inspection and qualitative evaluations, are contrasted and the expert on the basis of previous experience delivers an opinion (seldom quantified) on the questioned identity of the marks and, according to the uniqueness principle, on the corresponding author or producer. It is not infrequent to register opposite expert opinions upon the same evidence, and high level of error rates, not significantly different from those observed among untrained eyewitnesses' testimonies. Conversely, *forensic genetics* does not *seek individually distinctive features* in a genetic profile. Significantly, the genetic expert performs typings on the biological samples to be compared. In other words, each of the analyses assigns the sample (and its donor) to a group (not formally different from the classical ABO blood groups).

Genetic Theory and Probabilities

The foundations of the genetic theory have been laid almost 150 years ago by Gregor Mendel. The field of application is limited to characteristics, or observation units (from classical traits such as color or form, to the outputs of technologically sophisticated methods such as electrophoresis or mass spectrometry) for which the population under study shows discontinuous variation (i.e., the individuals appear as grouped into discrete classes, called *phenotypes*). The theory assumes that for each of these characteristics, a pair of genetic information units exists in each individual (*genotype*), but only one is transmitted to each offspring at a time with equal probability (1/2). So, for nonhermaphroditic sexually reproducing populations, each member inherits one of these genetic factors (*alleles*) paternally and the other one maternally; in case of both alleles are of the same type, the individual is said to be a *homozygote*, and *heterozygote* in the case the alleles are distinct. The theory further assumes that for each of the observable units (or Mendelian characteristics), there is a genetic determination instance (a genetic *locus*; plural: loci) where the alleles take place and that the transmission of information belonging to different loci and governing, therefore, distinct characteristics is independent. It is now known that for some characteristics, the mode of transmission is more simple and that not every pair of loci is transmitted independently, but the hereditary rules outlined above apply to the vast majority of cases.

These rules allow us to predict the possible genotypes and their probabilities in the offspring knowing the parents'

genotypes or to infer parents' genotypes given the offspring distributions. These predictions or inferences are not limited to cases where information on relatives is available. In fact, soon after the 'rediscovery' of Mendel's work, a generalization of the theory from the familial to the population level was undertaken embodied in what is now known as the *Hardy-Weinberg principle*. This formalism states that if an ideal infinite population with random mating is assumed, and in the absence of mutation, selection, and migration, the squared summation of the allele frequencies equals the genotype distribution. That is, if at a certain locus, the frequencies of alleles A1 and A2 are f_1 and f_2 , respectively, the expected frequency of the heterozygote A1A2 will be $f_1 \times f_2 + f_2 \times f_1 = 2f_1f_2$ (note that 'A1A2' and 'A2A1' are indistinguishable and are collectively represented by convention simply as A1A2); conversely, if the frequency of the homozygote for A1 is f_1 , the allele frequency would be the square root of this frequency (because the expected frequency of this genotype is $f_1 \times f_1$).

In order to apply this theoretical framework to judicial matters, it must be clear that 'forensics' implies conflict, a difference of opinion, which formally translates into the existence of (at least) two alternative explanations for the same fact. In the simplest situation, the evidence is explained to the court as (1) being caused by the suspect (the prosecution hypothesis) or, alternatively, (2) resulting from the action of someone else, according to the defense.

In order to understand how genetic expertise can provide means to differently evaluate the evidence under these hypotheses, a brief digression into the mathematics and statistics involved is therefore required. The first essential concept to be defined is probability itself. The probability of a specific event is the frequency of that event, or in more formal terms, probability of an event is the ratio of the number of cases favorable to it, to the number of all cases possible. It is a convenient way to summarize quantitatively our previous experience on a specific case and allows us to forecast the likelihood of its future occurrence. But this is not the issue at stake when we move to the forensic scenario – the event *has occurred* (both litigants agree upon that) but there is a disagreement on the causes behind it, meaning that the same event can have different probabilities according to its causation.

Let us suppose that a biological sample (a hair, organic fluid, etc.) not belonging to the victim is found in a homicide scene. When typed for a specific locus, it shows the genotype '19', as well as the suspect (provider of a 'reference sample'). If allele 19 frequency in the population is 1/100, the probability of finding by chance such a genotype is thus 1/10 000. Therefore, under the prosecutor's hypothesis (the crime scene sample was left by the suspect), the probability of this type of observations ($P|H_1$) is 1/10 000. While assuming the defense explanation (the crime scene sample was left by someone else), the probability of the same observations ($P|H_2$) would be $1/10\,000 \times 1/10\,000$. In conclusion, the likelihood ratio takes the value of 10 000 (to 1), which means that the occurrence of such an event is 10 000 times more likely if both samples have originated from the same individual than resulting from two distinct persons (again provided the suspect does not have an identical twin). Note that this likelihood ratio is often referred as 'probability of identity,' although it is not a probability in the strict sense.

Genetic Information and DNA

Forensic genetics was developed well before the establishment of both the chemical basis and the structure of the genetic material and direct analysis of DNA for forensic purposes had still to wait for many technological advances. Before this revolution, loci were just abstract entities and the molecular bases of the observable differences were not ascertained. Genotypes were inferred from phenotypes in controlled experimental conditions (in humans, passive experiments in which the transmission rules were assessed in bona fide families), defining genetic markers, such as the first one used in forensics, the ABO system of blood groups. Although the typings were robust and reliable, these indirect genetic analyses had many limitations and disadvantages. On the one hand, the number of genetic polymorphisms amenable to forensic applications was very limited and, consequently, their informative power; moreover, they could provide data ethically sensible, such as those related to individual health status. The ability to directly assess DNA individual differences in genomic regions devoid of coding capacity, that is, without expression in terms of visible or clinically relevant characteristics removed such difficulties and limitations.

DNA analysis confirmed that genetic information is digital, directly resulting from the chemical nature of its repository, composed by a variable sequence of units, symbolized by A, T, G, and C. This implies that at a particular location of the genetic sequence, an individual is defined by a pair of occupation states out of a very finite set of possible choices. In the simplest case, he/she would be either A/A, A/T, A/G, and so forth, each of these pairs defining his/her genotype. To achieve a satisfactory probability of distinguishing any pair of individuals, we must analyze a good number of positions in the genetic material (to generate a profile) for which of them the population diversity has been previously found to be reasonably high. The validated routine forensic genetic analyses currently employ a preparative technique (PCR, polymerase chain reaction) that specifically detects (and amplifies) short regions of DNA from our genome. The regions currently used have been selected according to two criteria: (1) to correspond to

noncoding tracts – that is, there is, to our knowledge, no information contained there and so no physical or psychological characteristics of the individual can be inferred from its analysis; and (2) to be highly polymorphic – that is, the DNA sequence is quite variable.

In conclusion, although proceeding conceptually and methodologically in a opposed way to the uniqueness principle common to other forensic sciences, in modern forensic genetics, the typing of a modest number of these markers in a individual results in a genotype constellation that turns out to be, in practical terms, almost unique (provided no identical twins are involved), that is, the chance of finding two random individuals with the same profile with a standard battery is less than one in a trillion.

DNA Extraction and Quantification

DNA Extraction

The process of isolating purified nuclear and/or mitochondrial DNA from both forensic specimens (blood, semen or saliva stains, hairs, muscle, bones, teeth, etc.) and reference samples (buccal swabs, blood spots on FTA, or liquid blood) is a crucial step to DNA profiling. Advances in forensic DNA extraction systems have been aimed at increasing the efficiency in the amount of purified DNA recovered (free from **polymerase chain reaction** (PCR) inhibitors) and automating the process for high-throughput analysis while maintaining a high integrity of the DNA molecule.

Currently, the validated methods for DNA extraction most widely used in forensic laboratories can be classified into three groups on the basis of their purification strategies: organic (phenol–chloroform) extraction, solid-phase DNA extraction methods (silica based), and ionic chelating resins (Chelex). Specific procedures using some of these basic DNA isolation principles (or a combination of them) have been developed depending on the type of sample source. These include the differential lysis procedure for the selective extraction of sperm cells, special procedures for bone and teeth DNA extraction, the procedure for DNA purification on reference biological samples spotted on FTA paper, or previous selection of specific cell types by laser-capture microdissection coupled with DNA extraction.

Automated DNA extraction procedures with different robotic platforms have also been implemented in forensic labs for high-throughput sample preparation, avoiding manual errors while improving sample tracking and reproducibility. Quality standards for DNA extraction in forensic labs include preventive measures against DNA contamination as well as the use of appropriate positive and negative controls for monitoring (Figure 1).

Organic (Phenol–Chloroform) Extraction

Organic extraction has been one of the DNA extraction methods most used in the forensic field. The first step of any DNA extraction assay is the breakdown of cell membranes and proteolytic digestion in the presence of sodium dodecylsulfate (SDS), and proteinase K. DNA is first purified by mixing thoroughly the cell lysate with a phenol–chloroform solution followed by centrifugation in order to separate the organic phase, where proteins become trapped, from the supernatant aqueous phase, where DNA remains. DNA in the aqueous phase is further purified by precipitation with ethanol and finally resuspended in a low-salt buffer.

For maximal DNA recovery and purity, the organic method protocol developed in many forensic labs involves a filtration purification step of the aqueous phase (instead of ethanol precipitation) using Centricon, Microcon, or, more recently, Amicon filter devices for DNA washing and concentration by

centrifugation through membranes with different pore sizes (30–100 kDa) (Millipore, Billerica, MA). Although this method is very efficient for the recovery of double-stranded high-molecular-weight DNA free from PCR inhibitors, it is time-consuming, requires multiple tube transfers, and is difficult to automate.

Solid-Phase DNA Extraction Methods

This extraction method is based on the ability of DNA to bind to silica in the presence of chaotropic salts such as guanidinium thiocyanate, sodium iodide, and guanidinium hydrochloride. Typically, cells are first lysed with proteinase K to release the DNA and then a binding buffer containing a chaotropic salt is added to prepare DNA for adsorption to the silica at pH < 7.5. Once DNA binds to silica, unwanted impurities can be rinsed away after subsequent washing steps, DNA may be eluted under alkaline conditions and low salt concentrations.

The silica method can be carried out in two different formats: silica columns and silica-coated paramagnetic beads. In the first case, after DNA binding in the column, washing of impurities and DNA elution are made by centrifugation. In the magnetic beads procedure, washing steps and DNA elution are facilitated simply by applying a magnetic force without the need of centrifugation devices.

Magnetic bead-based purification is currently one of the procedures best suited for DNA isolation in the forensic field as it enables rapid DNA purification with very efficient removal of PCR inhibitors, and it is suitable for high-throughput extraction using robotic platforms.

Chelating Resins (Chelex)

A rapid and inexpensive procedure for DNA extraction that has become popular in the forensic field is the use of chelating resins, such as Chelex 100 (Bio-Rad Laboratories, CA). These resins can bind divalent ions such as Ca^{2+} and Mg^{2+} deactivating unwanted nucleases and, therefore, protecting DNA molecules from cleavage. In most protocols, forensic samples are added to a 5% Chelex suspension, boiled for several minutes, and then centrifuged to remove the resin leaving DNA in the supernatant.

Unfortunately, the boiling procedure of chelating resins denatures DNA and yields single-stranded DNA that can be analyzed only by PCR-based methods. On the other hand, the DNA purity is not as good as that obtained with the organic extraction or the solid-phase procedures.

DNA from FTA Spots

FTA® is an acronym for Fast Technology for Analysis of nucleic acids. It consists of a cellulose-based matrix treated with a weak

Figure 1 Flowchart of most common Forensic DNA extraction methods.

base, a chelating agent, an anionic surfactant or detergent, and a uric acid (or a urate salt). Biological samples, such as blood or saliva, can be applied to FTA cards whose chemicals lyse cells and the released DNA remains immobilized. This system provides DNA preservation avoiding nuclease damage and microbial development, allowing a long-term storage at ambient temperature under dry conditions. FTA is at present a procedure widely implemented by several forensic laboratories for DNA collection of reference saliva or blood samples.

There are two main strategies for DNA extraction from FTA paper. One is to wash out proteins and cellular debris from the FTA spot, keeping the DNA bound to the FTA, and then use a clean paper punch to perform the PCR analysis. Alternatively, DNA can be eluted from FTA by a Chelex extraction or other procedures using the eluted DNA for further analysis.

The main advantages of FTA are the feasibility of automation and its long-term preservation due to its storage capabilities under ambient temperature.

Differential Lysis

A specific protocol for the selective separation of epithelial cells DNA from sperm DNA in sexual assault cases was developed in 1985 by Peter Gill. The procedure is a modified version of the organic extraction method based on the resistance of sperm nuclei to be lysed in the absence of a reducing agent such as dithiothreitol (DTT). The protocol involves a first lysis step in the presence of SDS and proteinase K aimed to release the female epithelial cells DNA in the supernatant. The washed pellet of sperm cells are subsequently lysed by treatment with SDS, proteinase K, and DTT and the sperm DNA is recovered from the supernatant of this second lysis fraction. The success

of this method to separate sperm DNA from vaginal cell DNA depends on the relative number of each cell type and the conditions of preservation of the forensic evidence. Failure to separate the male and female fractions by this procedure results in a mixed DNA profile.

DNA Extraction from Bones and Teeth

Several specific protocols have been described for DNA extraction from bones and teeth. All of them entail two primary steps. Previous preparation of compact bone tissue or teeth's dentine powder by pulverization in liquid nitrogen using a freezer mill, and the use of high concentrations of ethylenediaminetetraacetic acid (EDTA) to demineralize the hydroxyapatite matrix making osteocytes or odontocytes accessible to lysis. Early forensic protocols performed demineralization of bone samples by extensive EDTA washes before the lysis step with the subsequent loss of cellular material during different washing steps and high risk of sample contamination. More recently, a number of protocols have been developed for complete demineralization during the lysis step (using a lysis buffer containing 0.5 M EDTA), resulting in full physical dissolution of the bone sample and maximal recovery of DNA. Bone or teeth powder lysates are then submitted to organic extraction followed by Amicon filtration or purified by silica solid-phase procedures.

Laser Capture Microdissection

Laser capture microdissection (LCM) is a technique that allows to select and collect specific cell types. It is of particular interest

in the forensic field for specific sperm cell separation from mixtures of biological fluids in sexual assault cases. It combines existing light microscopic instrumentation with laser beam technology. There are two general methods of LCM: ultraviolet (UV) cutting systems and infrared (IR) capture systems. While in the IR system, after visualization of the cells of interest via microscopy, they are isolated by transfer of laser energy to a thermolabile polymer with formation of a polymer–cell composite. In the UV system, cells can be selectively captured by photovolatilization of cells surrounding the target cells. In both methods, captured sperm cells are transferred to a vial for DNA extraction. The LCM technique is used particularly in unbalanced mixtures in which very low levels of sperm cells are mixed with a high content of epithelial cells of the victim. As the number of captured cells is usually very small, the DNA extraction process is usually done by cell lysis in a small volume in the presence of proteinase K and a nonionic detergent such as Tween 20. Subsequent inactivation of the proteinase by a heat shock in the same vial of capture is carried out to finally obtain the DNA for downstream PCR analysis, minimizing the possibility of contamination and preventing the loss of DNA that could occur during the procedures for DNA purification.

Automation of DNA Extraction

Development of robotic platforms for the extraction of DNA has been fundamental in ensuring a high-throughput processing of both reference samples and forensic evidences as well as guaranteeing reproducibility and sample tracking. Automation has been implemented in many forensic labs dealing with DNA profiling from large batches of reference samples for inclusion in national DNA databases. Automation has also taken great interest in disaster victim identification cases, enabling laboratories to speed up the process of DNA identification of missing persons.

Most of the DNA extraction robots are based on solid-phase procedures with paramagnetic beads. There are several robotic stations for both small-scale and high-throughput processing as well as validated specific protocols for automated extraction of reference samples (blood, saliva, and FTA) and forensic samples (semen stains, blood, saliva, hair, bones, etc.). EZ1 (Qiagen), Maxwell 16 (Promega), and Automated Express (Life Science) are examples of small-scale platforms for automated DNA extraction of 6–16 samples simultaneously using paramagnetic beads, which have been validated for forensic samples. While the Tecan Freedom EVO automated liquid-handling workstation and the Beckman 2000 robot workstation are high-throughput platforms that can handle up to 96 samples at a time and are also validated for forensic analysis.

Microfluidic DNA Extraction Devices

The development of miniaturized devices for DNA preparation, manipulation, and analysis at the micron (microtechnology) or submicron level (nanotechnology) has become one of the most active research areas in molecular biology. They offer several advantages over conventional techniques that include reduced sample and reagent consumption, high-throughput

and high-speed analysis, and easy automation and integration of different molecular analysis in a single biochip. In addition, microfabrication enables labs to increase the detection limit with the potential to manipulate DNA at the level of individual molecules with very important implications for the analysis of traditional challenges (DNA mixtures, low copy number, etc.) in forensic genetics. In respect to this technology, silica solid-phase microchips have been developed for DNA extraction from forensic samples as well as some prototype microdevices for the differential lysis procedure.

DNA Quantification

Quantification of human nuclear DNA from forensic samples is a recommended procedure (FBI Quality Assurance Standard 9.4) for a reliable DNA profiling based on multiplex PCR amplification and capillary electrophoresis detection of short tandem repeat (STR) markers. The first purpose of nuclear DNA quantification is to adjust the DNA input (around 0.5–1 ng of DNA template) in subsequent multiplex PCR–STRs assays for optimal performance. On the one hand, an adequate amount of DNA determination prevents PCR failures that are due to the absence of DNA or avoids STR–PCR artifacts, such as random allele dropout, produced by stochastic amplification effects from low-template DNA (LT-DNA) samples (under 100 pg of DNA). On the other hand, it prevents off-scale over amplification artifacts (including $n - 1$ peaks, increased stutter bands and pullup) associated with an excess of DNA input in the PCR. In addition, an accurate DNA quantification helps to prevent the unnecessary waste of DNA, especially important when analyzing LT-DNA samples.

Until recently, forensic laboratories have been using the slot-blot hybridization approach to target the D17Z1 locus, a highly repetitive alphoid primate-specific sequence, for DNA quantification in forensic casework. However, this methodology, with a detection limit above the limit of the STR profiling approaches, was often not sensitive enough to detect low-copy number forensic DNA samples. Moreover, the method is labor-intensive, time-consuming, and poorly suited to high-throughput sample flow.

Several studies have demonstrated the usefulness of real-time PCR using Taqman probes or SYBR Green chemistry for sensitive, specific, and high-throughput DNA quantification assays using autosomal, X & Y chromosomes, and mitochondrial DNA targets.

The development of commercially available real-time PCR human DNA quantification kits has also contributed to a worldwide use of real-time PCR in forensic genetics. Current DNA quantification kits are mainly based on three real-time PCR chemistries: the 5' nuclease activity assay using *Taqman* probes (Quantifiler Duo, Applied Biosystems), the Plexor chemistry using fluorescently labeled, iso-dC-containing primers (Plexor® HY System, Promega Corporation), or the use of Scorpion primers (Quantiplex Kit, Qiagen). Despite quantitation of total human DNA, these validated DNA assays offer qualitative data of great interest for forensic genetic typing: quantification of the presence of PCR inhibitors in the DNA extract, sex determination, and quantitative estimation of the proportion of the male component in mixtures of male and female biological fluids.

Current Real-Time PCR Chemistries for Human DNA Quantification

There are three commercial available fluorogenic chemistries to monitor the real-time progress of the PCR for the purpose of human DNA quantification that are validated for forensic samples: (1) by measuring the 5' nuclease activity of the *Taq* DNA polymerase to cleave a target-specific fluorogenic probe (a *TaqMan* probe: an oligonucleotide, complementary to a segment of the template DNA, with both a reporter and a quencher dye attached, that only emits its characteristic fluorescence after cleavage); (2) by measuring the decrease of fluorescence using one primer synthesized with an iso-dC residue as the 5'-terminal nucleotide linked to a fluorescent label and using dabcyI-iso-dGTP in the nucleotide mix (which pairs specifically with iso-dC) that quenches the signal of the fluorescent label primer when incorporates in the amplicons during the PCR; and (3) using scorpion primers that are bifunctional molecules containing a PCR primer covalently linked to a probe, which incorporates a fluorophore, and a quencher, which inhibits fluorescence. During PCR, when the probe binds to the PCR products, the fluorophore and quencher become separated leading to an increase in fluorescence.

The application of double-stranded DNA-binding dye chemistry, such as SYBR Green, to DNA quantification from forensic samples has also been described. One drawback of SYBR Green-based detection is that nonspecific amplifications (primer-dimer, nonhuman products, etc.) cannot be distinguished from specific amplifications. On the other hand, the amplicon/dye ratio varies with amplicon length. Furthermore, SYBR green can only be used in singleplex PCRs.

Real-time analysis of the fluorescence levels (increase or decrease depending on the chemistries) at each cycle of the PCR (amplification plot) allows obtaining a complete picture of the whole amplification process for each sample. In the initial cycles of PCR, a baseline is observed without any significant change in fluorescence signal. An increase in fluorescence above the baseline (or a decrease in fluorescence in case of Plexor HY System) indicates the detection of accumulated PCR product. The higher the initial input of the target genomic DNA, the sooner a significant increase (or decrease for Plexor HY System) in fluorescence is observed. The cycle at which fluorescence reaches an arbitrary threshold level during the exponential phase of the PCR is named Ct (threshold cycle). A standard curve can be generated by plotting the log of the starting DNA template amount of a set of previously quantified DNA standards against their Ct values. Therefore, an accurate estimation of the starting DNA amount from unknown samples is accomplished by comparison of the measured Ct values with the Ct values of the standard curve.

Real-Time PCR Nuclear DNA Quantification Assays

Two validated real-time PCR kits for human nuclear DNA quantification are currently used in the forensic DNA labs. Both kits allow simultaneous detection of one autosomal (single or multicopy) target (for total human DNA quantitation), a target of chromosome Y (for male human DNA quantitation),

and one internal PCR control (IPC) (to evaluate PCR inhibition) using Taqman (Quantifiler Duo) or Plexor Chemistry (Promega). More recently, a new kit based on Scorpion primers chemistry (Qiagen) have been validated in the forensic field targeting an autosomal multicopy marker and also including one IPC. Table 1 shows the different targets included in these validated real-time PCR kits.

Many other designs based on real-time PCR (mostly based on TaqMan chemistry) have been developed and validated in the forensic field to target single-copy autosomal markers, Alu repetitive elements, or X and Y chromosome-specific regions. The National Institute of Standards and Technology has developed a human DNA quantification standard (SRM 2372) intended for forensic applications that consists of three well-characterized human genomic DNA materials. The use of the same certified standard for human DNA quantification is expected to improve reproducibility across different laboratories and among different real-time PCR assays.

Real-Time PCR Mitochondrial DNA Quantification

The use of a Taqman real-time PCR assay for quantification of mitochondrial human DNA (mtDNA) from forensic specimens was first described by Andréasson et al. in 2002 by targeting a 142 bp region spanning over the genes for tRNA Lysine and ATP synthase 8 that can be amplified in a single PCR reaction or in combination with a nuclear DNA target. The specific quantification of human mtDNA by a Taqman real-time PCR assay of two different mtDNA fragment sizes (113 and 287 bp) within the hypervariable region I (HV1) of the mtDNA control region has also been described as a useful tool to evaluate the mtDNA preservation state (degradation) from ancient bone samples. A 69 bp fragment of the mtDNA NADH

Table 1 Targets included in real-time PCR forensic kits for nuclear human DNA quantification

<i>Real-time PCR kit</i>	<i>Human DNA target</i>	<i>Male DNA target</i>	<i>Internal PCR control</i>
Quantifiler Duo	RPPH1 (ribonuclease PRNA component H1) 140 bp	SRY (sex-determining region Y) 130 bp	Artificial template 130 bp
Plexor HY System	RNU2 locus (human U2 small nuclear RNA) 99 bp	TSPY gene (testis-specific protein Y encoded) 133 bp	Artificial template 150 bp
Quantiplex	Proprietary region present on several autosomes of the human genome 146 bp		Artificial template 200 bp

Quantifiler Duo and Plexor HY System allow simultaneous quantitative analysis of human and male DNA, while Quantiplex only permits to detect a human multicopy DNA target. Three kits include an internal PCR control to monitor PCR inhibition. The size of each amplicon is shown in base pairs (bp).

dehydrogenase subunit 1 (ND1) locus has also been used as a target for mtDNA quantitation in forensic specimens using a TaqMan duplex real-time PCR assay that allows simultaneous quantification of human nuclear DNA. Another mtDNA target used in forensics by a TaqMan-MGB assays is a 79-bp fragment of a conserved region of the human mtDNA, which is coamplified with an autosomal and a Y-chromosome target. Recently, it has been described a novel forensic utility of quantitative real-time PCR using TaqMan-MGB probes, targeting the highly variable mitochondrial single nucleotide polymorphism 16519T/C to investigate heteroplasmic mixtures with an accurate quantification of the minor allele down to 9%.

At this time, there is no commercially available real-time PCR assay for quantification of mtDNA nor has been developed a standard for mtDNA quantification in forensic materials. These seem to be some of the reasons why mtDNA quantitation is much less widespread in forensic casework.

Amplicon Polymerase chain reaction (PCR)-amplified DNA segment.

Autosomes/autosomal The chromosome component not related to sex determination (complimentary to the X and Y).

Capillary electrophoresis Separation of DNA fragments based on their size and by electroinjection into a capillary with a transparent window at a fixed distance from the injection position, where excitation by a laser allows 4–6 color signals to be read by a charge-coupled device camera at timed intervals.

CCD Charge-coupled device.

Di-, tri-, tetra-, and pentanucleotide repeats Short tandem repeat (STR) units comprising 2, 3, 4, and 5 base pair repeated DNA segments (alternatively termed units or motifs).

DNA sequencing Analysis of the base sequence of an amplified segment of DNA.

Multiplex A PCR amplification combining multiple DNA sites, i.e., markers, per reaction.

PCR and Cyclers Polymerase chain reaction, amplification of targeted DNA segments using site-specific primers, and heat-stable DNA polymerase. The PCR depends on cycled heating–cooling steps controlled by automated temperature cyclers.

The Genetics of Short Tandem Repeats. Short Tandem Repeats as a Class of Satellite DNA and the Genomic Characteristics of the Core Forensic Markers. Early Consensus on Ideal Forensic Short Tandem Repeats

A short tandem repeat (STR) consists of an array of tandemly reiterated, normally identical, multibase motifs (often termed repeat units or simply repeats) that vary in number. They belong to the common genomic element of repeat sequence or repetitive DNA, which ranges from small, single-site tandem repeat loci to much larger recurrent elements at multiple, genome-dispersed locations, such as SINES, LINES, and transposons. Tandemly repeated sequence is often termed satellite DNA because of atypical base composition changing DNA buoyancy in density gradient separations, giving three low-density satellite bands. The bulk of satellite DNA comprises repeats with numerous, long motifs creating segments up to 5 mb long, but two other types are much shorter: minisatellites have tandem repeats above 10 bases (bp) and reach 0.5–30 kb in length, and microsatellites–STRs have 2–10 bp repeats in very short arrays typically 20–100 bp long. The relatively short length of STRs is critical because it makes them the most amenable to amplification by polymerase chain reaction (PCR) and therefore ideal forensic markers. In contrast, minisatellites include DNA polymorphisms originally used in pioneering genetic fingerprinting techniques, but are too long to be amplified and therefore show markedly less forensic sensitivity.

Human STRs occur approximately once every 2 kb with the most frequent type composed of 2 bp, dinucleotide repeats. Dinucleotide STRs are widely used as linkage markers with chromosome-centered kits available, so have found their way into occasional relationship testing use. However, excessive PCR stutter with dinucleotide repeats (see the section ‘Irregularities Seen in Routine STR Profiling. Non-Standard Alleles, Complex Forensic STR Profiles and the Importance of Detection Thresholds’) means all forensic STRs comprise 3, 4, or 5 bp repeat motifs with most tetranucleotides (4 bp). **Figure 1**

summarizes the structure of TH01, a typical tetranucleotide forensic STR; genomic positions of 23 core and 15 supplementary STRs; and the proportion in humans of each repeat type. With ~200 000 potentially suitable tetranucleotide STRs, it is necessary to review how the current set of 23–38 was selected. First, the chromosome distribution of forensic STRs in **Figure 1** highlights the need for fully segregating positions across the genome and for same-chromosome (syntenic) pairs at well-separated sites. This characteristic was among the features considered ideal when originally choosing forensic STRs. Second, it was desirable to choose loci with high levels of variability but which had manageable repeat numbers giving short enough amplified fragments for robust and readily multiplexed PCR. STRs must ideally give comparable performance between shortest and longest repeats and can be easily accommodated in limited electrophoresis size windows. Third, a feature of STRs quickly seen as important was repeat sequence complexity. Early trials of STRs TH01 and SE33 in 15 laboratories demonstrated that simple STRs (e.g., TH01) with limited repeat numbers were much more reliably typed than complex loci typified by SE33 with numerous repeats comprising 2, 3, and 4 bp repeat motifs. The fact that complex repeat STRs tend to be more polymorphic required a balance to be struck between variability and repeat complexity, leading to choice of much less polymorphic TPOX and CSF1PO STRs, while SE33 has only recently undergone increasing readoption with an obvious value as the most discriminatory forensic STR. This partly reflects more precise electrophoretic resolution with modern capillary-based instruments where single base differences are more precisely measured than before. It is arguably the case that balancing complexity and variability had previously constrained marker choice, but as the current core 23 STRs are informative enough for nearly all forensic tasks, this did not become a major restriction. **Figure 2** gives a 1985–2010 timeline showing STRs introduced in gradually expanded sets. As the literature has lacked a clearly outlined STR set overview to date, **Figure 3** summarizes the relationship

Figure 1 (a) Principal genomic features of a simple forensic short tandem repeat (STR): TH01. (b) Chromosome distribution of 23 core forensic identification STRs, upper panel, and 7 + 8 supplementary STRs (Promega CS-7 and Qiagen Investigator HD, respectively) lower panel. (c) Ratio of repeat unit nucleotide numbers in the largest survey of human autosomes.

Figure 2 Timeline of development of landmark DNA analysis approaches, introduction of core identification short tandem repeats (STRs), forensic typing systems, and DNA database developments.

Figure 3 Overlapping and multiplex-specific short tandem repeat (STR) marker sets, core systems grouped leftmost (plus SE33, Penta D/E), and new supplementary STR multiplexes rightmost. Bold SGM/ESS/CODIS STRs are the original ESS set of seven loci and the lower five STRs in the ESS group are the extended ESS set. All national DNA database (NDNAD) regimes use sets of the 20 STRs shown on the left with the exception of the German NDNAD that includes SE33.

between all current forensic STRs, their kits, and the US vs European minimum or extended sets.

Lastly, it is important to note that STRs are common in all eukaryotic species and share the key characteristics of being abundant, short in length, and highly polymorphic, so they provide an ideal means to identify, establish kinship relationships, and infer population affinities in most animals, indeed in plants, as well as humans. Animal forensics such as pet-hair analysis therefore uses identical approaches (and shares the same interpretative problems) to those outlined below for human STRs.

The Principles of Forensic Dye-Labeled STR Typing: PCR Amplification, the DNA Profile, and the Match Probability

The STR typing system using dye-labeled PCR primers has stayed largely unchanged for at least 15 of the 20-year history of forensic STR analysis shown in [Figure 2](#). This is because the combination of capillary electrophoresis (CE) detection of dye-labeled fragments following PCR amplification of STR sequences creates a typing system, that is extremely sensitive; easily multiplexed; readily applied to poor or scant forensic sources of DNA using well-validated chemistry/instrumentation; and provides a direct relationship between the signal strength and the amount of DNA molecules put into the amplification. This latter characteristic is crucial to detecting low levels of DNA in both single-source evidential material and in detecting mixtures, so that necessary adjustments can be made to pursue further amplifications, or in mixtures, to the profile interpretation framework so

allelic components of individual contributors can be identified. In the early stages of STR typing development, the main limiting factors were perceived to be level of multiplexing possible in single-tube reactions, electrophoretic resolution of single-base allele differences, actual size ranges of amplified fragments, and instrument sensitivity/signal quality. In this section, the typing process is outlined and the efforts to overcome these original limitations are detailed. The section titled '[Irregularities Seen in Routine STR Profiling, Non-Standard Alleles, Complex Forensic STR Profiles and the Importance of Detection Thresholds](#)' reviews common irregular patterns (not strictly problems) encountered in forensic STR typing.

PCR amplification was the single-most important step forward in forensic DNA analysis, leading to greatly improved sensitivity for STR typing compared to the original genetic fingerprinting techniques and therefore considerably widening the scope of biological contact traces amenable to analysis. Primer sequences recognize a unique genome sequence to focus on this target STR segment alone. Amplified fragments or amplicons, therefore, comprise a DNA segment containing the unique primer sequence (one strand dye labeled), the repeat region of variable length, and the intermediate sequences between primer and repeats. Largely due to their short size and the relative uniformity of chosen loci, STRs have proved to be extremely robust components of PCR multiplexes. Multiplexing requires comparable reaction dynamics per primer pair – notably the T_m or optimum temperature that primers can bind specifically to their recognition sequences. Similarly, the small size differences between shortest and longest repeat alleles provide more balanced rates of amplification across all size ranges. Lastly, PCR cyclers developed in the mid-1990s using more precise Peltier temperature control have provided greatly improved reliability and more consistent performance – both between cyclers and within their temperature transfer plates. This led to much more predictable amplification when applying suitably prepared commercial PCR kits of optimum primer sets, high-performance DNA polymerase, buffer, and reaction components. Early consensus on best-performing, forensically ideal STRs also helped to accelerate production of well-balanced multiplex kits. However, possibly of more benefits to forensic STR analysis was the accompanying improvement in the instruments available to detect and size the amplified STR fragments.

Early in the development of forensic STR typing, instruments created for automated DNA sequencing were adapted to analyze STR amplicons. Using sequencing dyes and instrumentation meant for the four colors, each originally dedicated to one base terminator, were available for PCR fragment analysis – three for amplicon labeling and one (red) for a standardized size ladder. Use of dedicated size standards focused on short base pair ranges allowed accurate size estimation from a mobility reference curve. This is made for size standards corun in each capillary and minimizes the effects of mobility variation between samples. The blue, green, and yellow dyes are readily attached to the end of one PCR primer without interfering with amplification efficiency. Therefore, it was a straightforward step to extend multiplexing up to four STRs per dye label by combining markers with nonoverlapping amplicon size ranges. A dual fragment X–Y gender marker based on a 6 bp sequence deletion in the X chromosome

amelogenin gene is included in all kits. Depending on total repeats, 3–4 STRs can be divided across a size window of ~100–400 bp. However, this represents the original strategy of arranging actual amplicon sizes to span the window. More recently, mass modification using ‘drag-chute’ elements within the primers or nonspecific sequence tails (Figure 1 shows a 2 bp primer tail for TH01) allows more precise size range adjustment, so that amplicons can be miniaturized yet still occupy upper size ranges, while potentially extra STRs can be accommodated. Furthermore, the number of dyes available has risen to five, further extending the multiplex ceiling by ~20% more STRs with an orange dye now used for sizing.

The resulting DNA profiles consist of multiple peaks corresponding to dye-labeled amplicons passing a laser and charge-coupled device (CCD) camera at the read window at recorded time intervals. While profiles can be individually reviewed by STR and by dye, most are automatically analyzed by analysis software that recognizes peaks in prescribed positions for each allele derived from a concurrently run reference ladder of the common repeat variants. These positions vary minimally between capillaries but more between runs and instruments – a rule-of-thumb being ± 0.5 bp – but most procedures can adequately use one or two allele reference ladders per run of up to 96 samples. Rare alleles comprising unusual repeat numbers or intermediate repeat structures (such as 1, 2, and 3 bp repeat motifs among regular tetranucleotide alleles) are not usually included in allele ladders, but rare alleles generally migrate to positions that can be correctly aligned and named. Excessive sequence variation among the repeat region motifs can lead to irregular mobility so that same-size fragments with very different underlying sequence migrate differently. This characteristic represents a potential drawback for SE33, but all other forensic STRs have more regular motif structures and, therefore, show almost entirely predictable mobilities.

As STR typing is a single reaction in one tube, it provides major benefits compared to other forms of forensic analysis. First, the dye-labeled amplicons generate peak heights and their ratios in direct proportion to the input DNA – giving a system for inference of likely preamplified DNA levels and making mixture interpretation of simple two-donor multiple-peak profiles a viable option. Second, minimal tube transfers are involved in the protocol: sample to extraction tube, extract to PCR tube, and amplicon to CE sample plates – so STR analysis has relatively low sample switch rates compared to other forensic protocols. Lastly, the system has considerable potential to be streamlined and quickened. As a result, there is an interest in utilizing faster acting polymerases, shorter cycles, and direct DNA input (i.e., lysing cells in the PCR tube).

The statistical analysis of profiles is the last of the major features of STR analysis that provided a quantum shift in ease of use and quality of data compared to previous forms of DNA profiling. STRs brought limited size-range discrete alleles, eliminating the complexities of reporting continuous patterns of DNA mobility where the much longer alleles of DNA fingerprint microsatellites required placement in broad, loosely defined, continuous mobility windows. In effect, STRs have mobility variation windows less than 1 bp so each allele can be precisely differentiated. This provides a simple system to construct a profile frequency because the population allele frequency estimation on which it is based is accurate and

much more representative of the true patterns of variability than before. As the composite STRs in a profile have been chosen to be independently segregating and extensive testing continues to suggest they are neutral loci (not subject to changes in allele frequencies within a population due to selection), their allele frequencies can be combined to provide an unbiased single likelihood of the profile in the population. Figure 4 shows an example profile with composite locus frequencies combined to form a final profile frequency. This value can be used to report a random match probability (RMP) (one over the profile frequency) representing the chance of an identical profile in unrelated individuals from the same population. The issue of which populations to use is still sometimes contested, but the ease with which a range of population data can be accessed by a laboratory to prepare different likelihoods helps address arguments that hindered proper assessment of STR statistics in early court cases. Further population statistical refinements have been added, notably use of theta adjustments for population stratification. A common initial courtroom challenge to STR population data was the problem that allele frequency estimates based on broad population group estimates might be unrepresentative of smaller, often isolated, subpopulations from which a defendant may originate. Therefore, without suitable adjustment, allele frequencies tend to underestimate those of subpopulations and the rarity of the profile is artificially exaggerated. A theta value of 0.01–0.02 is now commonly applied to compensate for the potential of allele frequency underestimation in subpopulations.

Irregularities Seen in Routine STR Profiling. Nonstandard Alleles, Complex Forensic STR Profiles, and the Importance of Detection Thresholds

Irregularities encountered with routine profiling of normal forensic DNA can be divided into two types: arising from the genetics of the STR and caused by the PCR or CE detection process. The observation of complex STR profiles is a different phenomenon and concerns the difficulties of interpreting profile patterns seen when amplifying low-level DNA (herein LCN) or mixed source DNA from different donors. Genetic irregularities are rare and largely manageable since invariably only one composite STR is affected. Particular features of the signal peaks in a profile arising from PCR or CE are also manageable but can often be overlooked by laboratories if insufficient attention is paid to establishing laboratory-specific detection thresholds from experimental and routine profile data. This has a direct bearing on the interpretative framework used to analyze LCN DNA or mixed profiles because appropriate detection thresholds are needed to properly define the limits of allele detection possible from such complex profiles. Progressive improvements in both sensitivity of CE instruments and PCR performance from reformulated kits means complex profiles are seen more often in routine criminal case-work as LCN DNA is now amplified to detectable levels much more frequently.

Genetic-based STR irregularities include repeat slippage mutations, genomic null alleles (that may be kit-specific), tri-allelic patterns, sequence-based mobility shifts, and off-ladder

Figure 4 Characteristics of a typical 16-short tandem repeat (STR) multiplex profile generated by the Promega ESX-17 kit. The labeled gray bars above each peak set denote the size windows of the majority of recorded alleles in that STR represented in the reference allelic ladder. The inset graphic top right shows a *pop.STR* population frequency output example for D3S1358 and the lower table the component genotype frequencies for all 16 STRs in two population groups. The cumulative product of the individual genotype frequencies: the profile frequency and random match probability (RMP) are calculated for each population.

alleles including intermediate repeats and interlocus alleles. STR repeat slippage mutations are created when DNA is copied and a repeat is lost or gained due to the cell's polymerase slipping when aligning copied strands in meiosis (uncommon or undetected in mitosis). Mutation is therefore largely confined to the germ line, that is, occurring in gametogenesis and detected comparing related individuals. Slippage, therefore, affects interpretation of relationship testing results, but is notably much more common in STRs than other variant loci, for example, single nucleotide polymorphisms (SNPs). Slippage typically occurs in single STRs at variance with the other results but can occur in multiple loci – particularly when combining STRs with higher mutation rates such as SE33. This becomes a significant problem when only a deficient pedigree is available to test and a wrongly named first-degree relative of the true father (e.g., brother) shows few STR exclusions. This represents a principal application for the supplementary STRs shown in Figure 3. In criminal STR profiling, null and nonstandard alleles are the main genetic irregularities, consequently *STRbase* includes reference libraries collating variant alleles, triallelic patterns, and null alleles listed by typing kits compared. In terms of routine typing, the main issues with variant allele definition are length estimation compared to reference ladders and assignment of a suitable allele frequency. Figure 5 shows two examples for nonstandard STR alleles, an off-ladder allele

and a mobility-shift variant, illustrating single base-pair resolution generally provides a robust system for recognizing rare variants. The allele can often be verified by coelectrophoresis with a reference spike, for example, combining a common TH01 9.3 with a rare 10 allele (particularly when paired with an inconveniently distant heterozygote allele such as a 6). In research terms, the US National Institute of Standards and Technology (NIST), the host organization of *STRbase*, endeavors to sequence a proportion of variants reported to their web site. Interlocus alleles falling between reference ladder spans can be difficult to assign to a particular STR if both are homozygous, but one simple approach is to review allele frequencies of each homozygote to deduce which is more likely, then pair the variant accordingly. Null alleles occur when a primer-binding sequence harbors a deletion or an SNP close to the 3' end and would be undetectable if all kits used identical primers. In this case, a heterozygote with a null variant on one chromosome would show an apparent homozygous allele for the other – albeit commonly at detectably lower signal heights. However, forensic STR kits from different manufacturers use multiple primer designs; hence, deletions or SNPs in primer-specific locations show nulls as a homozygote (or more rarely imbalanced heterozygote peaks) not seen in the alternative primers, so these are often termed kit discordancies. Note that deletions may occur in intermediate sequences

Figure 5 Two examples of nonstandard short tandem repeat (STR) alleles. D2S441 peaks indicate an unequivocal 13 allele and a peak falling between the expected 11.3 and 12 repeat allele size windows possibly due to sequence variation causing mobility shift. SE33 peaks have the allelic ladder superimposed above. The off-ladder (marked OL) peak indicates a likely 12.2 allele but with a size estimate closely matching an inferred position (closest ladder alleles = 12 and 13, 301.29 and 305.5 bp, respectively).

(between primer and repeats) specific to a primer set as well as in primer-binding sites. Kit discordancies have obvious consequences for database searches of profiles typed with an alternative primer set to the database entries. At the moment, there are increasing efforts to manage the scrutiny of discordancies by parallel typing of large cohorts of population samples since nearly all deletions and SNPs are rare. Manufacturers can also address many of the more common discordancies by incorporating redundant primers (multiple recognition sequences) binding to the variant sequence and recovering the repeat allele on that chromosome. Mobility shift due to sequence variation is an ongoing problem in complex STRs, but the successful inclusion of SE33 in the German NDNAD suggests that laboratories can readily cope with sequence microvariation.

PCR and CE factors can create profile irregularities, but a well-optimized STR protocol should produce clean profiles, while a properly established dye wavelength matrix will eliminate the main problems of signal linearity limits (signal overload) and signal pull-up from cross-dye detection interference. In nearly all cases, complex profiles are a consequence of the nature of the input DNA. They present considerable interpretative challenges and are covered in-depth in other articles regarding LCN and mixtures. An important point is that complex profiles inevitably lead to differences in interpretation among experts and, therefore, disagreement between prosecution and defense specialists in court. As a very generalized summary, LCN profiles can have signals close to or below levels normally classified as noise and tend to show allele and locus drop-out (loss of matched peaks) and/or allele drop-in (spontaneous appearance of random, unmatched alleles). Mixed profiles reveal themselves as more than two alleles in a proportion of STRs and detectable peak imbalances. Therefore, establishing certain detection thresholds is an essential preparation for differentiating artifact signal from allele detection signal in complex profiles. The key thresholds are stutter, peak height ratio (PHR), analytical threshold (AT), and stochastic threshold (ST). Thresholds should be properly gauged by all STR typing laboratories for their input DNA, PCR regimes, kits, and CE instrumentation. At the time of writing, consensus has been reached about how to instigate this process and comprehensive guidelines are now in place for this critical aspect of STR analysis.

Stutter is a PCR artifact caused by polymerase slippage during PCR creating a detectable peak –4 bp shorter/faster than the allele peak, generally 5–15% of allele peak heights. A much weaker +4 bp following peak can also occur. PHR measures the normal heterozygote peak-pair ratio limits based on screening of signal balance in a broad range of normal crime-case profiles. AT sets a minimum peak height below which an allele assignment becomes unreliable since it is imbedded in background noise signals. Despite being easy to establish with negative controls or nonpeak area measurements, most laboratories use a default 50 relative fluorescent units. However, increased PCR success with LCN DNA leads to fewer negative profiles and more showing peaks at or below the AT. Therefore, proper AT preparation increases the reliability of assigning alleles from LCN signals. Likewise, LCN PCR is highly prone to stochastic effects where one strand amplifies preferentially at random and heterozygotes consequently show marked imbalance and can only be reliably recognized with reference to the laboratories routine PHR range. Extreme heterozygote imbalance is manifested as one allele failing to amplify completely despite signal from the other and requires establishing the ST. ST measures the highest surviving peak height seen when drop-out is known to occur based on experimentally reproduced LCN analyses, such as dilution series. ST records a limited range of maximum homozygote peak heights seen when the paired alleles drop out. Therefore, a thorough knowledge of ST and PHR values is a key to differentiating LCN stochastic effects from normal heterozygote peak ratio imbalance. Stutter and PHR are clearly the key factors in mixture interpretation and luckily both are easily established from any previously recorded CE data.

For mixture interpretation, laboratories can establish their own mixture ratio limits – predetermined major/minor peak ratios that are considered sufficiently differentiated to allow assignment of alleles to different contributors. Simple ranges of control DNA artificial mixtures provide an adequate means to begin introducing mixture detection limits. A simple mixture rule-of-thumb divides a profile into three zones: the 5–10% of observed highest peak of the stutter zone; the 10–70% mixture zone (i.e., peaks outside of PHR values); and the signal zone >70% of the highest heterozygote peak. A debatable issue in establishing minimum levels of stutter and PHR is

Figure 6 The balance between forensic operational needs, levels of certainty, and numbers of short tandem repeats (STRs) typed in routine or supplemented analyses. Reproduced with the kind permission of Kristen O'Connor from: O'Connor KL, Butts E, Hill CR, Butler JM, and Vallone PM (2010). Evaluating the effect of additional loci on likelihood ratio values for complex kinship analysis. In: *Proceedings of the 21st International Symposium on Human Identification*. San Antonio, TX, 10–14 October.

whether these are recorded for whole profiles, per STR, or per allele. For example, stutter levels for TH01 9.3 alleles are much lower than the other alleles and different STRs show varying stutter and heterozygote ratios. A final cautionary note is that thresholds are not set in stone but require constant maintenance based on evolving cycling conditions, kit formulations, and instrument performance – creating an almost continuous validation process for laboratories tackling LCN analysis and mixture interpretation.

New Developments in STR Typing

Space does not allow thorough coverage of latest developments in STR typing, but it is important to be aware of areas that merit further development. These include rapid PCR, portable STR analysis, ancestry inference, and mass spectrometric STR typing permitting detection of repeat region sequence variation. Rapid PCR potentially allows amplification reactions shortened from 3 h to ~40 min. Proof-of-principle studies indicate using more rapidly activated polymerases and three- to sixfold reductions in cycling times works well. The prospects for mobile, real-time STR typing technologies for rapid screening at the scene of crime or point of arrest are also promising. A study of the viability of a system known as melting curve detection using multiple allele fluorescent probes showed that STRs D18S51, TH01, and D8S1179 could be typed with this potentially portable system, although discrimination is compromised by use of just three STRs. The potential for ancestry inference from STR data, use of mass spectrometry to type STRs, and detect sequence changes within repeat motifs are covered in other articles of this work.

Beyond the Core Loci: New STRs

Figure 6 reflects how the numbers of STRs routinely used may soon be dictated by new operational needs such as familial

searching and improving relationship testing statistics in identification of missing persons – when pedigrees are incomplete or bridge several generations. This raises the issue of whether additional STRs should now be assessed or be available to the DNA laboratory when more discriminatory information is required in certain scenarios. It is important to note that the supplementary STRs detailed here offer considerable scope for exploiting the sixth dye potentially available in Applied Biosystems 3500 CE instruments.

An extra 14 STRs have recently been released in two kits: Promega CS-7 7-plex (five novel STRs including Penta C) and Qiagen Investigator HDplex 12-plex (nine novel). Additionally, a first population-tailored STR, D6S1043, is a part of the SinoFiler™ kit (Applied Biosystems) available to East Asian laboratories. The genomic positions of these extra STRs shown in Figure 1 indicate some close proximities for certain syntenic pairs, but a detailed genetic map of 39 forensic STRs is now available to help address linkage issues. It should be noted that adding more STRs does not always solve the problem of ambiguous relationship likelihoods in complex pedigrees. Furthermore, allowance must be made for the degree of linkage between established and novel STRs when occasionally expanding STR typing for the analysis of close relatives.

Lastly, NIST has developed a 26-component mini-STR set, designed from the start to be typed from very short amplicons and easily accommodated into relatively narrow size windows. Three STRs have since been incorporated in the extended ESS set, while one component shows inconsistencies, providing 22 STRs that are potentially highly sensitive for analyzing degraded DNA.

Accreditation in Forensic DNA Analysis

R Decorte, University Hospitals Leuven, Leuven, Belgium; KU Leuven, Leuven, Belgium

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Accreditation Procedure in which an external agency recognizes formally a laboratory or an individual to be competent for performing specific tasks.

Accuracy The degree of correlation between a measured value and an accepted reference value or the value obtained by a previous method.

Audit A systematic and independent review in order to determine if the activities and results conform with established standards.

Calibration A series of tests under specified conditions to demonstrate that an instrument or device produces results within specified limits by comparison to those produced by a traceable standard.

Certification Procedure in which a third party provides a written proof that a product, a process, or a service meets certain requirements.

Precision The repeatability or reproducibility of individual measurements expressed as standard deviation (SD) or relative standard deviation (CV).

Probe A short single-stranded DNA segment which is tagged with a reporter molecule (radioactive phosphorus or nonradioactive biotin) and complementary to a given target in the genome.

Proficiency test A test to evaluate the competence of the technicians and the performance of a laboratory; tests can be blind in which the lab does not know that it is being tested,

or open so that the technicians are aware they are being tested; internal proficiency tests are organized by the laboratory itself, while external proficiency tests are organized by an external agency independent of the laboratory.

Quality assurance Systematic procedures implemented by the laboratory to ensure accuracy and reliability of the tests performed.

Quality control Internal procedures used to monitor the quality of the tests performed; external established standards or known test reagents (positive and negative) can be used as controls.

Reference material A generic term for a substance or material whose property values are known and fixed, and are certified by an external organization.

Reproducibility The precision of the methodology to produce results under different conditions or at different time points.

Sensitivity Capacity of the test to detect small quantities of a substance.

Specificity The degree of uniformity of the response to the substance in question.

Validation A series of tests performed to check if a methodology or instrument meets certain pre defined criteria set by the laboratory or the company who provides the test or instrument.

Introduction

In 2010, it was 25 years ago that Alec Jeffreys published his paper describing the use of DNA analysis in an immigration case. DNA fingerprinting (as it was called) was an important step forward in forensic identification and over several decades, forensic DNA technology has become a major tool in the fight against crime. As with any new technology that is introduced in forensic evidence analysis, DNA fingerprinting or profiling (as we call it now) has been challenged in the early days in the courtroom, especially in the United States. One of the most fundamental aspects of American jurisprudence is the adversarial system where the two parties, prosecutor and defense, confront the jury and the judge with the evidence for and against the defendant. This judicial system uses several standards to evaluate the admissibility of new or novel scientific evidence in court. In the first U.S. criminal case (*State of California v. Andrews*, 1988) where DNA profiling was presented, the results of DNA analysis performed by Lifecodes Corporation were admitted but the statistical evidence was excluded because the prosecution could not validate it. In a retrial (after a hung jury), the court admitted both pieces of evidence applying the 'Rule 702 reliability test' and the

'Downing relevance test.' The latter standard was established in 1985 and gave the court the possibility to exercise a pretrial hearing in case of a serious question concerning the reliability of the evidence. In another case (*State of New York v. Castro*, 1989), the admissibility of DNA evidence was critically questioned. Lifecodes Corporation analyzed a bloodstain on the suspect's watch (Joseph Castro) and the DNA profile of the victim matched that from the bloodstain. The defendant swore that the blood was his own, which the prosecutor wanted to counterattack with the DNA evidence. After a pretrial hearing where different expert witnesses from both the prosecution and the defense presented a review of the DNA evidence, the New York Supreme Court decided that the DNA identification theory and practices are generally accepted in the scientific community, and that forensic DNA identification evidence meets the 'Frye standard.' However, the Court ruled the inadmissibility of the DNA evidence because Lifecodes did not use generally accepted scientific techniques for obtaining their results. Several flaws were observed in their procedures, including probe contamination, inappropriate controls, and inconsistent matching rules. This case highlighted the needs for standardization of practices and uniformly accepted methods for quality assurance (QA).

The need for QA was further emphasized by proficiency studies in 1987 and 1988 conducted by the CACLD in which a high rate of false positives (incorrect sample loading and sample mixing) and false negatives (inability to identify a mixture) were reported due to laboratory error. The FBI responded in 1988 by creating a TWGDAM, or SWGDAM since 1999) in order to establish peer-consensus standards for forensic DNA testing. This group has established over the years guidelines for QA, proficiency testing, and interpretation, and has sponsored several interlaboratory studies. By 1989, the number of questions (e.g., legal, ethical, and reliability) concerning forensic DNA typing has risen to such an extent that the National Research Council (NRC) of the National Academy of Sciences (NAS) volunteered to address the general applicability and appropriateness of DNA technology in forensic science including issues of standardization and data management. A first report (NRC I) appeared in 1992 with recommendations in six separate areas: technical considerations, statistical interpretation, laboratory standards, databanks and privacy, legal considerations, and social and ethical issues. The committee's recommendation concerning laboratory error was: "Laboratory errors should be measured with appropriate proficiency tests and should play a role in the interpretation of results of forensic DNA typing." Furthermore, in a reaction to a newspaper article published by the *New York Times* about the report, the NRC responded: "We regard the accreditation and proficiency testing of DNA typing laboratories as essential to the scientific accuracy, reliability, and acceptability of DNA typing evidence in the future. Laboratories involved in forensic DNA typing should move quickly to establish quality-assurance programs." It was not until 1998 that the DNA Advisory Board (DAB; established by the FBI after approval of legislation (DNA Identification Act) in the US Congress in 1994) came with separate but overlapping sets of QA standards for forensic DNA testing laboratories and convicted offender DNA databasing laboratories. The DAB also stated that there is a need for a mechanism to ensure compliance with these standards. They recommended that forensic laboratories performing forensic DNA analysis seek accreditation to demonstrate compliance with the standards and, therefore, ensure quality control (QC).

The requirement for accreditation of forensic DNA typing laboratories has been embedded in specific legislation concerning forensic DNA analysis in several countries and is one of the requirements in these countries for conducting forensic DNA analysis in criminal cases. However, many countries, such as the United States, do not have a mandatory system but rely on voluntary accreditation. In February 2009, the NAS in the United States released a report 'Strengthening Forensic Science in the United States. A Path Forward' that was critical of the forensic system in the United States. The report pointed, with the exception of DNA analysis, to a lack of consistency in procedural standards, training, accreditation, and overall research in forensic fields such as fingerprint, fire-arms identification, and analysis of bite marks, blood spatter, hair, and handwriting. The NAS report also formulated some recommendations, especially mandatory accreditation and certification for forensic laboratories and their personnel.

Accreditation or Certification?

Establishing a QA system in a laboratory should help to ensure that the results provided by the laboratory and its personnel are reliable and accurate. This can be achieved by implementing and maintaining a quality management system that describes in detail the efforts the laboratory takes for obtaining reliable results and for reducing the chance of error, but which also should lead to improvements in the laboratory and personnel processes. External assessment of this quality system by an impartial authority can lead to accreditation or certification if the quality system meets defined standards of performance, competence, and professionalism. An individual forensic expert can only be certified if he or she meets criteria concerning education, training, and competence, which can be demonstrated by documentation and examination. Individual certification has certain advantages for the legal system as it proves the competence to report DNA typing results, or present and discuss these results in court. However, it is inadequate to evaluate the competence of the laboratory that provides the results. Certification of individual experts can be voluntary (e.g., United States – American Board of Criminalistics) or mandatory (e.g., Netherlands Register of Court Experts) as part of legal requirements.

A laboratory can become certified or accredited if it meets predefined standards. According to a 2004 survey conducted by the European Network of Forensic Science Institutes (ENFSI), 17 members out of 53 were accredited, the majority (14) according to ISO/IEC 17025 standards or 'national regulation.' ISO/IEC is a joint initiative of the International Organization for Standardization (ISO), a network of national standards institutes in 162 countries, and the International Electrochemical Commission (IEC). Two ENFSI members reported that they were accredited according to ISO 9001:2000 and ISO 9002 standards that have been developed by ISO. These ENFSI laboratories were apparently not aware that they were not accredited but 'certified according to ISO 9001' (ISO 9002 was replaced by ISO 9001 in 2000). ISO 9001 (current version 2008) is an international standard providing a set of requirements for a quality management system with the purpose to satisfy client needs. A certificate can be obtained after a successful audit performed by an external agency accredited for performing these assessments.

ISO/IEC 17025 (current version 2005) is a standard that specifies the general requirements of competence for a laboratory or institution to carry out tests and/or calibrations, including sampling. It is applicable to any laboratory that performs testing or calibration activities irrespective of the scientific field where the laboratory is active. Regulatory and safety requirements (e.g., laboratory safety) on the operation of laboratories are not covered by ISO/IEC 17025. Compliance with these requirements is regulated locally. Laboratories that comply with ISO/IEC 17025 will also operate in accordance to ISO 9001. However, certification only for ISO 9001 does not demonstrate the competence of the laboratory to produce reliable and reproducible results. Accreditation, according to ISO/IEC 17025, is a more comprehensive approach to assure the reliability of the test results and is also seen as the international standard for forensic laboratories. Accreditation of forensic DNA testing is mandatory in several countries around the

world because of specific requirements in DNA legislation. On 30 November 2009, the European Council Justice and Home Affairs (Council Framework Decision 2009/905/JHA) reached an agreement on a framework regarding mandatory accreditation of forensic service providers carrying out laboratory activities in fingerprinting and DNA profiling. The purpose of this framework is to ensure that forensic laboratory results obtained in one European Union (EU) member state are recognized by the law enforcement authorities in all other EU member states. This decision means also that a common international standard (ISO/IEC 17025:2005) is introduced for forensic service providers within the EU but this standard will not apply to any measures taken outside a laboratory (e.g., sampling at the scene of crime). EU member states should implement these decisions in their legislations by 30 November 2013 for DNA profiling and by 30th November 2015 for dactyloscopic data.

In the United States, accreditation has been mostly voluntary except for some states (New York, Texas, and Oklahoma). In 1982, the American Society of Crime Laboratory Directors/Laboratory Accreditation Board (ASCLD/LAB) offered a voluntary forensic laboratory accreditation program known as the 'Legacy Program.' This program contained statements of principles describing acceptable levels of performance and the criteria of evaluation. These criteria were divided into essential (91 standards that directly affect and have a fundamental impact on the laboratory or the processed evidence), important (45 standards that are key indicators of the overall quality of the laboratory but do not directly affect the product or the evidence), and desirable (16 standards that have the least effect on the product or the processed evidence and will improve the professionalism of the laboratory). A forensic laboratory was accredited by the ASCLD/LAB Board of Directors if it met 100% of the essential criteria, 75% of the important criteria, and 50% of the desirable criteria. In 2009, the ASCLD/LAB announced that it would no longer accredit laboratories through its 'Legacy Program.' Instead, ISO/IEC 17025:2005 compliance (ASCLD/LAB International) is endorsed and all labs previously accredited by ASCLD are required to comply with the international standard no later than 31 March 2014. The criterion rating system of the 'Legacy Program' has been abandoned by ASCLD/LAB and each lab should comply now with the numbered requirements of ISO/IEC 17025:2005. As of 7 June 2012, ASCLD/LAB has accredited 390 forensic laboratories including 17 international (Singapore, Canada, New Zealand, Malaysia, and Hong Kong) and 24 private laboratories, with 216 laboratories accredited under the 'International Testing Program.' Forensic Quality Services Inc. (FQS; the ANSI (American National Standards Institute) - ASQ (American Society for Quality) National Accreditation Board has acquired FQS Inc. on 29 November 2011) is another accreditation body in the United States which provides accreditation to ISO/IEC 17025 since 2004. Up to June 2012, 60 laboratories have been accredited by FQS.

The quality system of the FBI laboratory relies on the requirements described in ISO/IEC 17025:2005 in addition to supplemental standards of ASCLD/LAB. These standards can be helpful in the process of setting up a QA program in a forensic laboratory as the requirements in ISO/IEC 17025 are stated in general terms. However, the ASCLD/LAB standards cannot create additional criteria to ISO/IEC 17025, but can be

used as a guideline for the interpretation of the requirements. Other forensic laboratories use the ILAC Guide 19:2002 'Guidelines for Forensic Science Laboratories' as a guide to implement an ISO/IEC 17025 quality system. In addition to these guidelines, forensic laboratories can also use the recommendations of the Paternity Testing Commission (PTC) of the International Society of Forensic Genetics (ISFG). The PTC has formulated in 2002 explanations and recommendations for paternity testing laboratories concerning certain requirements of the ISO/IEC 17025 standard.

A Short Guide to Accreditation for ISO/IEC 17025

Accreditation is a process of comparison and evaluation of a (forensic) laboratory's operations against the requirements (e.g., ISO/IEC 17025:2005; [Table 1](#)). It relies on QC and QA. QC refers to measures taken to ensure that the laboratory analysis and interpretation meets a specified standard. QA refers to measures taken by the organization (laboratory) to monitor, verify, and document its performance, and to minimize the occurrence of error. The QA system includes internal procedures (e.g., redundant testing), regular external proficiency testing, and regular internal and external auditing of laboratory operations. A laboratory audit might be the evaluation of certain procedures (internal) or the entire operation of a laboratory (external). Records of the assessment describe the findings of the audit and may lead to a course of corrective actions that have to be taken in order to resolve any problem or deficiency in the standard requirements observed during the audit. The findings of the audit are graded, which reflects the type of action (immediately, within a certain period, or none) a laboratory has to take in order to resolve the remarks made. The laboratory has to present a 'plan of action' with defined deadlines for resolving the remarks and will get its accreditation only after approval of this plan by the audit team. Accreditation is limited in time (3–5 years) and is controlled annually by the same audit team that did the inspection for the first application for accreditation. A laboratory can extend its accreditation, which is obtained after a full inspection usually by a new team of assessors.

Establishing a QA system in a laboratory is the first step toward accreditation. While only 17.3% of the European forensic institutes in the 2004 survey of ENFSI were accredited according to ISO/IEC 17025, 50% of the institutes had a QA system available and another 44.2% were in the process of development. A QA system should at least have good documentation of all processes in the laboratory, including validated and documented procedures (standard operating procedures or SOP), tested reagents, calibrated equipment, appropriate control samples, and detailed documentation of the operations, results, and interpretations. In particular, a good QA system focuses on minimizing the risk of errors and establishing methods for detecting errors. Having a QA system in place is a good starting point on the track to accreditation as many aspects of the ISO/IEC 17025 requirements might be already covered ([Table 1](#)). Some of these aspects are trivial but others require more explanation, especially with regard to the forensic field. These items include control of records (4.12), personnel (5.2), accommodation and environmental

Table 1 Key categories of requirements in ISO/IEC 17025:2008

1. Scope – general requirements for the competence of the laboratory to carry out tests/calibrations, including sampling
2. Normative references – cited references with regard to standards
3. Terms and definitions – clarification of terms and definitions
4. Management requirements
- 4.1 Organization – the laboratory must meet the requirements of ISO/IEC 17015, the needs of the customer/client, the regulatory authorities, or the organizations providing recognition
- 4.2 Quality system – the laboratory shall establish, implement, and maintain a quality system appropriate for the activities of the laboratory
- 4.3 Document control – the laboratory shall establish and maintain procedures to control documents (design, approval, and changes) that are part of the quality system (quality manual, operation manuals, standard operating procedures (SOP), etc.)
- 4.4 Review of requests, tenders, and contracts – the laboratory shall establish procedures and policies so that both clients/customers and laboratory understand the requirements and that the laboratory has the capacity to perform the work
- 4.5 Subcontracting of tests and calibrations – any subcontracting should be performed by a competent subcontractor after informing the client/customer
- 4.6 Purchasing services and supplies – the laboratory shall establish procedures and policies for the selection and purchasing of supplies and services that can affect the quality of the tests of the laboratory
- 4.7 Service to the client – requesting customer feedback (positive and negative) in order to improve the quality system and the service to the client
- 4.8 Complaints – the laboratory shall establish procedures and a policy for the resolution of complaints received internally (personnel) and externally (clients)
- 4.9 Control of nonconforming testing and/or calibration – the laboratory shall establish procedures and a policy to deal with testing/calibration that do not conform to the SOP of the laboratory or the agreed requirements of the client
- 4.10 Corrective action – the laboratory shall establish a procedure and policy (including the designation of appropriate authorities) for implementing corrective action when problems are identified (nonconforming work or departures from the policies in the quality system); the procedure should include an analysis of the cause, selection, and implementation of the corrective action, monitoring of the corrective actions, and need for additional internal auditing
- 4.11 Preventive action – procedures must be in place to direct preventive actions against nonconformances, either technically or against the quality system; any preventive action should be covered with action plans for implementation and monitored to reduce the likelihood of the occurrence of such a nonconformance and to take advantage of the opportunities

(Continued)

conditions (5.3), test and calibration methods and method validation (5.4), and assuring the quality of test and calibration results (5.9).

Control of Records

In a quality system, all procedures performed from the receipt of the samples until the reporting of the results of the testing must be documented. Any action in the laboratory process

Table 1 (Continued)

- 4.12 Control of records – the laboratory shall establish and maintain procedures concerning records (quality and technical) including identification, collection, access, storage, maintenance, and disposal
- 4.13 Internal audits – the laboratory shall have a predetermined schedule and procedure to conduct periodically internal audits; all elements of the quality system should be covered, including all testing activities
- 4.14 Management reviews – the laboratory's top management is required to review the performance of the quality system and testing systems periodically according to a predefined schedule to ensure the suitability and effectiveness of the system, and to introduce necessary changes and improvements; ISO/IEC 17025 directs a number of topics that must be covered during the review
5. Technical requirements
- 5.1 General – the laboratory shall take account of factors that can influence the correctness and reliability of the tests performed or to be developed
- 5.2 Personnel – the management of the laboratory is required to ensure the competence of the personnel who operates the equipment, performs the tests, or writes the reports; a training program should be established that is relevant to the work performed
- 5.3 Accommodation and environmental conditions – a laboratory must provide an environment that will facilitate the correct performance of the testing
- 5.4 Test and calibration methods and method validation – a laboratory must use appropriate methods and procedures including methods for sampling, in order to assure correct results; methods that have been appropriately validated and published are recommended
- 5.5 Equipment – the laboratory must have the necessary equipment to accomplish the correct sampling and measurement, and to assure the correct performance and accuracy of the tests
- 5.6 Measurement traceability – equipment used for tests should be calibrated; calibrations or measurements should be traceable to international standards; reference materials must be traceable to certified reference materials (if possible)
- 5.7 Sampling – the laboratory shall have a sampling plan and procedures for sampling when part of a substance or a sample is used for testing
- 5.8 Handling of test and calibration items – the laboratory shall establish procedures for the transportation, receipt, handling, protection, storage, retention, and disposal of test items including provisions to protect the integrity of the test, and to protect the interests of the laboratory and the client
- 5.9 Assuring the quality of test and calibration results – a laboratory should have quality control procedures for checking and monitoring the validity of the tests
- 5.10 Reporting the results – a laboratory should report the results of all tests including all the information requested by the client and necessary for the interpretation of the test results; results should be reported accurately, clearly, unambiguously, and objectively, and opinions and interpretations must be clearly marked in the report

should be recorded so that these actions are traceable to the person (analyst, examiner, or reporting scientist) who has performed the actions. Where appropriate, observations or test results must be preserved with photographic records (e.g., examination of evidence objects), printed or electronic scans (e.g., electropherograms of DNA profiles). Manual corrections should be recorded and documented through interpretation guidelines. In general, the information in these records should be such that another competent person can

evaluate and interpret the data in the absence of the examiner/analyst who has done the analysis. This independent evaluation of the results has been implemented in most forensic laboratories in order to assure the validity of the interpretation of the results. This process should be documented and the records should indicate who has done these controls. All these aspects are similar to the chain of custody of evidence objects and must assure that any review of the laboratory case records allows reconstructing the process each evidence object has gone through in the laboratory.

Personnel

ISO/IEC 17025 requires that the laboratory defines the minimum requirements of the different staff members, including qualifications (e.g., education), job description, and a documented training program for new staff. Local regulations may require that staff members, who are responsible for reporting the results, must be certified according to certain criteria. Both DAB and ISFG (PTC) have made recommendations concerning laboratory directors, technical managers, or scientists who are authorized to sign reports: (1) education should be at least at the level of a master's degree in the relevant area (e.g., biology or human genetics for DNA analysis); (2) experience of at least 3 years in a competent forensic (or paternity) DNA testing laboratory must be demonstrated. The PTC also included that experience must be documented with at least 100 reports covering all major aspects of paternity testing. In addition, the DAB recommends for examiners/analysts a minimum bachelor's degree, at least 6 months of forensic DNA laboratory experience, and successfully completing a qualifying test, whereas for technicians, a training program and successfully completing a qualifying test with respect to their job responsibilities would be required. In addition, the laboratory must have a policy for training and education in order to keep the competence of the personnel at the level of current and future developments. The efficiency of these actions should be monitored. The ENFSI DNA working group has also published a Concept Training Document with minimum recommendations for training and competence testing of staff.

Accommodation and Environmental Conditions

Owing to the sensitive information of forensic evidence analysis, it is inevitable that the laboratory facilities and evidence storage must be properly secured and that access is restricted. Special care is needed in order to prevent cross-contamination, which can be done by physical separation of different activities or separating analysis processes, for example, reference samples are processed (DNA analysis) by analysts who do not examine evidence objects. In addition, the examination of evidence objects in a single forensic case might need separate examination in space or in time (e.g., evidence objects from the suspect versus evidence objects from the victim). As current forensic DNA analysis methods rely on DNA amplification (PCR), it is necessary to take steps to prevent contamination with PCR products by dividing the laboratory into at least three different work areas: examination of the evidence objects and DNA isolation (pre-PCR), work areas for PCR setup (pre-PCR), and work areas for handling of PCR products (post-PCR).

Special attention must be given to the avoidance of contamination from post-PCR areas to pre-PCR areas. This can be accomplished by using strict procedures for organization of the laboratory work: an analyst who starts the day in a post-PCR work area cannot do any work in a pre-PCR area the same day, while the reverse is still possible if the analyst continues his/her work in the post-PCR area after working in a pre-PCR area. The ISFG (PTC) has recommended that a laboratory should have procedures for monitoring potential contamination from PCR products, which includes also validated decontamination procedures. With respect to contamination, it is also necessary to focus on procedures for monitoring (and decontamination) of disposable plasticware and reagents used in the analysis procedures.

Test and Calibration Methods and Method Validation

A laboratory performing forensic DNA testing should use methods, including methods for sampling, that are appropriate for the analysis. The ISFG (PTC) has recommended using DNA systems for which proficiency testing is available and the population distribution data is available. Laboratory-developed methods and nonstandard methods, including equipment and software (commercially available or in-house developed), should have been validated before they can be used in routine casework. This does not mean that commercially developed test kits, which have been validated (developmental) by the manufacturer, can be used by a forensic laboratory without further validation. A laboratory should always do an internal validation of these kits in order to ensure that the laboratory is able to reproduce the specifications (e.g., sensitivity and specificity) set by the manufacturer on equipment used by the laboratory. The validation process should start with a written procedure of the analysis (draft version of a SOP), setting objectives for the validation, and defining requirements for accepting the validation. The results must be analyzed appropriately (including statistical evaluation) after the experimental procedures, and formally reported with a conclusion (e.g., acceptance, rejection, and additional validation necessary) concerning the validation. Typical studies of internal validation of DNA systems (short tandem repeats or STRs) in forensic testing include determining reproducibility, precision for sizing the alleles, sensitivity, and mixture studies. The ISFG (PTC) has recommended the following list for validation of methods: (1) using reference standards or reference materials; (2) comparison of results achieved with other methods; (3) interlaboratory comparisons; (4) systematic assessment of the factors influencing the results; (5) assessment of the uncertainty of the results based on scientific understanding of the theoretical principles of the method and practical experience. The ENFSI DNA working group has also published a list of minimum criteria that could serve as a guideline in the validation of various aspects of DNA profiling.

Assuring the Quality of Test and Calibration Results

A laboratory must have procedures for monitoring the quality of the procedures and test results, including calibration of equipment used in the analytical procedures. Calibration should be traceable to international standards or by using

certified reference materials. A laboratory should use proper positive and negative controls in its analytical procedures where positive controls are (preferably) traceable to international standards or certified reference material. The National Institute of Standard and Technology in the United States provides reference materials for DNA profiling (STR and mtDNA) and DNA quantitation that can be used for validations or for monitoring the performance of the lab. Laboratories should participate in interlaboratory comparisons or proficiency testing programs. The laboratory should set up an internal QC or testing program if certain methods or DNA systems are not covered in these external programs. This also includes the type of samples for which a laboratory has obtained accreditation. Bones, tissue samples, and hair are typical samples not included in external proficiency DNA testing programs. The laboratory should analyze these samples at least once a year in order to evaluate the lab's performance in typing these samples. Typically some samples that have been analyzed previously are typed a second time by the analyst without knowledge of the previous results for these samples.

Both DAB and ISFG (PTC) have recommended participating in a proficiency testing program at least twice a year. Blind proficiency testing is generally considered the best way to evaluate the performance of a laboratory. They are, however, difficult to set up if the laboratory does not know that it is part of a testing program. In this case, it requires cooperation from official authorities (police and/or justice) in order to disguise the test as a 'routine' case, which may lead to ethical and legal problems. For this reason, current blind proficiency testing programs are based on the distribution of standard material to all participants in the program and on a grading system of the test results. There are several providers of forensic proficiency testing programs of which Collaborative Testing Services Inc. (CTS) and the German DNA profiling group (GEDNAP) are used by most forensic laboratories in the United States and Europe, respectively. CTS, since 1978, is a commercial provider of proficiency tests in several fields of forensic testing and is recognized by ASCLD/LAB. The DNA test samples are usually two reference blood stains and two questioned stains. Laboratories are requested to report the test results, including DNA profiles and body fluid identification (only when information given with the samples does not include the source of the cell material), and to give an interpretation (inclusion, exclusion, or inconclusive) based on the test results. After evaluation of the results of the participating laboratories, an extensive report with the results of all the participants is made available. GEDNAP is the German-speaking group of the EDNAP group, which was established in 1989 with the aim to harmonize DNA profiling in Europe. The blind trial of GEDNAP is organized by the Institute for Forensic Medicine in Münster (Germany) with the following aims: (1) standardization of methods and procedures; (2) standardization of nomenclature; (3) evaluation of the competence of the laboratories to obtain correct results; (4) elimination of errors in typing. Each participant in the program receives two series of samples each consisting of three reference samples and four questioned samples. The questioned samples are designed to reflect real casework samples with respect to type, size, and material. Laboratories are requested to give information concerning the analytical procedures used and the DNA profiles obtained,

including the raw data. The laboratory will receive a report in which every allele call has been graded: (1) no errors; (2) mixture not detected; (3) error in typing but would not be reported; (4) error in typing, which would be reported. Type 4 errors are considered to be true errors in the final evaluation and the laboratory receives a certificate for the DNA systems, which were correctly typed. The results of internal QCs and from proficiency testing must be analyzed by the lab in order to report the performance of the laboratory. Any observed problem or error should lead to planned actions in order to correct the problem or prevent it from happening again.

Single-Nucleotide Polymorphisms

C Børsting and N Morling, University of Copenhagen, Copenhagen, Denmark

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Electrophoresis A method for separation of molecules based on their size and electrical charge.

Hardy–Weinberg equilibrium A locus is in Hardy–Weinberg equilibrium, when allele and genotype frequencies in a population remain constant from generation to generation.

Heterozygosity The fraction of individuals in a population that is heterozygous for a particular locus.

Match probability The probability that two unrelated individuals have the same genotype.

Multiplex PCR/SBE Standard PCR or SBE reactions involving multiple targets.

Nucleosome A DNA–protein complex that forms the basic unit of DNA packaging.

Polymerase chain reaction A method for generating millions of copies of specifically selected DNA sequences from just a few copies of DNA.

Single-base extension A method for determining the identity of a single nucleotide at a specific position in a DNA sequence. The method is also known as minisequencing.

Abbreviations

bp Base pairs
CE Capillary electrophoresis
CODIS Combined DNA index system

PCR Polymerase chain reaction
SBE Single-base extension
SNP Single-nucleotide polymorphism
STR Short tandem repeat

Introduction

Single-nucleotide polymorphisms (SNPs) are base pair (bp) variations at specific locations in the genome. Per definition, a genetic variation at a single bp locus is not considered to be an SNP unless at least two alleles have frequencies of more than 1% in a large population of unrelated individuals. The haploid human genome consists of approximately 3 billion bp. The number of SNPs is estimated to be 10–11 million, which gives an average of one SNP per 275 bp. The vast majority of SNPs have only two alleles because the mutation rate at a particular bp position is extremely low and it is highly unlikely that two point mutations happen at the same position over time. For this reason, SNPs have been used extensively to map the history of populations by identifying the distribution of SNP alleles among existing and past populations. SNP markers are also the best choice for construction of a dense set of polymorphic markers that can be used for studying the association between the markers and a particular trait or disease.

SNPs have many potential uses in forensic genetic investigations, including estimation of ethnicity, human traits, or diseases. These issues are addressed in other articles of this book. Here, the use of SNPs for human identification is discussed.

SNPs Versus Short Tandem Repeats

Short tandem repeats (STRs) have been the preferred markers for forensic genetic investigations since the 1990s, and today, standardized commercial kits with STRs are used by forensic

laboratories across the globe. Below, the advantages and disadvantages of STRs and SNPs are compared.

Power of Discrimination

One SNP locus is less informative than one STR locus, because SNP loci have only two possible alleles and the STR loci typically used in forensic genetics have 8–15 different alleles. The match probability P for n SNP loci can be approximated as a simple function of n and the frequency of the least common allele, ρ , by assuming that all SNPs are in Hardy–Weinberg equilibrium and that ρ is constant for all loci:

$$P = (\rho^2)^n + (2\rho(1-\rho))^n + ((1-\rho)^2)^n$$

The match probability has the highest value for $\rho = 0.5$ but does not change very much when ρ is 0.3–0.5. If ρ is between 0.2 and 0.5, 50 SNPs give a combined match probability equivalent to that of 12 STRs. Thus, panels of SNPs that can match the commonly used STR panels, for example, the 13 combined DNA index system (CODIS) loci or the 12 European standard set loci, should include at least 50 SNPs with a minimum heterozygosity of 0.32 ($\rho = 0.2$) and a preferable heterozygosity of 0.42 ($\rho = 0.3$) or higher.

Mutation Rates

Mutations pose a major problem in relationship testing. A mutation may result in a genetic inconsistency between the child and a parent, and even though the parent matches the child at all other investigated loci, the conclusion will be

ambiguous and the results may speak in favor of two or more likely scenarios. Relatives share a high number of alleles and only a few genetic inconsistencies are expected between a child and, for example, an uncle or a grandfather. Therefore, genetic inconsistencies between a child and an alleged parent could be due to mutations, and the alleged parent could be the true parent, or the results could indicate that the alleged parent was a close relative of the true parent.

The mutation rates of the commonly used STRs are typically 0.001–0.003, whereas the mutation rates of SNPs are estimated to be 0.00000001. Mutations are present in one of the 13 CODIS loci in approximately 3% of all mother–child–father trios. In contrast, mutations will be extremely rare if SNPs are investigated.

Amplicon Lengths

When a cell dies and the content is spilled into the surroundings, DNA is quickly degraded into smaller pieces. The rate of the degradation process varies depending on temperature, humidity, pH, light, presence of microorganisms, and other environmental factors. It is generally believed that the DNA in nucleosome complexes are better protected from degradation and a distinct pattern of nucleosome-sized fragments are observed as the degradation progresses. The length of DNA in the nucleosome core is 146 bp, and it is difficult to amplify longer fragments by conventional polymerase chain reaction (PCR) in highly degraded DNA.

The length of the PCR product with an SNP locus needs only to be the length of the PCR primers plus 1 bp (the SNP position). PCR primers are usually 15–18 bp long, and thus, a PCR product containing an SNP locus may be shorter than 40 bp. In contrast, the commonly used STR alleles have up to 40 tandem repeat units, each with a size of 4 bp, and consequently, PCR products containing an STR locus can measure 200 bp or longer. Furthermore, STRs are usually detected by electrophoresis, and in order to separate and identify all the loci in one experiment, the longest PCR products in the commercial multiplexes should be as long as 400–450 bp. Consequently, partial STR profiles are frequently observed when the DNA is highly degraded, whereas SNP typing of the same material results in complete profiles (see [Figure 2](#) for example).

In mass disasters such as the World Trade Center terrorist attack in 2001 or the South Asian Tsunami in 2004, the victims may be impossible to identify by visual inspection because the remains are highly fragmented, decomposed, or burned. Recovered DNA may be highly degraded, and if reference materials from the missing persons are not available, the victims must be identified via reference samples from close relatives. The low mutation rate of SNPs and the possibility of typing highly degraded DNA make SNPs very useful in mass disaster investigations. SNPs were used for human identification at the World Trade Center attack, but the SNP assay was still in a test phase and the results were predictably poor. Only assays that are properly validated and preferentially used routinely by the investigating laboratories should be used in the chaotic and stressful environment of a mass disaster.

PCR Artifacts

PCR artifacts known as stutters are generated during the PCR amplification of tandem repeats. Stutters formed by amplification of the STRs commonly used in forensic genetics are usually one repeat shorter than the target sequence, but stutters of other lengths are sometimes observed. It has been proposed that stutters are formed when unfinished extension products dehybridize from the target DNA during elongation and subsequently anneal to the STR sequence in another position (known as slipped-strand mispairing). Usually, the stutter peak is much lower (<10%) than the peak originating from the parent allele in the electropherogram. However, if the number of initial target DNA molecules is low and the stutter is formed during the first critical cycles of the PCR, there is a risk that the stutter peak may be as high as the parent peak and it may be misinterpreted as a true allele and assigned to the sample. Furthermore, unfinished extension products will be formed in higher numbers when PCR is performed on highly degraded DNA because PCR primers will anneal to strands where the target sequences are interrupted. Stutters are also a major problem in the analysis of mixtures because it can be difficult to conclude whether a small peak in a stutter position is in fact a stutter or an amplification product from another individual that contributed less to the mixture.

Stutters are not formed in the amplification of SNP loci. Even if unfinished extension products are formed by slippage or because the target DNA is highly degraded, the unfinished extension products can only anneal to one unique position and it will simply function as a primer in the next PCR cycle.

Databasing

National and international databases contain millions of STR profiles from known criminal offenders, victims, and trace samples collected from crime scenes over a period of more than two decades. It would be an overwhelming task to type all these samples again to create a similar SNP database, and in some cases, it will be impossible, because the samples have been used up or discarded and cannot be replaced. Therefore, STRs will most likely remain the preferred markers in crime casework and SNPs may be used only as a supplementary tool in future crime investigations. In relationship casework, the profiles are not stored for future use, and it may become more common to use SNPs instead of STRs, especially because of the low mutation rate of SNPs (see [Mutation Rates](#)).

Mixtures

SNP loci are not very informative when the sample contains DNA from more than one person, which is something frequently observed in trace samples from crime scenes. If both SNP alleles are detected in the mixture, there is no discriminatory power at that locus and any individual may have contributed to the mixture. The SNPs for forensic panels are selected because they are highly polymorphic, and therefore, there is a high probability that both alleles will be detected in mixtures of two or more individuals. If one of the individuals who contributed to the mixture is homozygous at a particular locus, there is $\rho^2 + 2\rho(1 - \rho)$ percentage chance (75%, if $\rho = 0.5$) that

another individual in the mixture has the other allele. With STRs, it is possible to estimate the number of contributors in the mixture from the number of detected alleles, and sometimes it is even possible to estimate the STR profiles of the minor and major contributors based on the amplification strength of the alleles. None of this is possible with SNP loci.

SNP Typing Methods

The increasing interest in SNPs shown by many different scientific disciplines during the last 20 years has resulted in the continuous development of SNP typing platforms. In general, these platforms employ one of the four common technologies: hybridization, primer extension, ligation, or invasive cleavage. Some platforms are high-throughput platforms that can type thousands of SNPs from a few individuals or a few SNPs from thousands of individuals at the same time and at a low cost. Within the forensic community, there has been a great interest in these technologies because many forensic laboratories have experienced a large increase in samples that need to be processed and, at the same time, there has been an increased demand for faster and cheaper investigations. Unfortunately, the high-throughput SNP platforms have not been developed specifically for forensic purposes. Typically, these platforms use 10–200 ng of DNA per sample per experiment, which is an acceptable amount if the sample is taken in the form of, for example, blood or a buccal swab from an individual. However, it is a lot more DNA than typically recovered from trace samples at crime scenes. In forensic genetics, high sensitivity is pivotal and investigations must be successfully completed from very small amounts of DNA (typically 100–500 pg). Therefore, the attempts to implement high-throughput SNP platforms for routine forensic genetic investigations have so far been unsuccessful. Instead, the SNP typing assays developed for forensic genetics are based on the low-throughput PCR–SBE–CE protocol described below. This method is highly accurate and sensitive, and it can be performed with the same instruments used for standard STR analyses.

SNP Typing by PCR–SBE–CE

SNP typing assays developed for forensic genetic purposes usually involve an initial multiplex PCR followed by a multiplex single-base extension (SBE) reaction and detection of the SBE products by capillary electrophoresis (CE). A multiplex PCR is a standard PCR except that multiple fragments are amplified simultaneously. This reduces the time and cost of the assay, and importantly, it reduces the amount of sample material that is required. Multiplexing of up to five fragments is usually feasible without difficulty. However, as the number of desired products increases, there is an increased risk of formation of primer dimers and unwanted amplification products. Furthermore, it becomes increasingly difficult to ensure that all fragments are amplified equally efficiently and extensive optimization of large multiplexes is usually required.

The SBE reaction is performed as consecutive cycles of denaturation of the PCR products, annealing of the SBE primers to the PCR products, and SBE (Figure 1). The SBE primer anneals to the single-stranded PCR product immediately

Figure 1 Diagram of the PCR–SBE–CE protocol. Fluorescently labeled ddNTPs are shown as bold letters (A, C, G, and T). The colors of the letters correspond to the dye windows in the electropherogram (see Figure 2).

upstream of the SNP position, and the DNA polymerase adds a fluorescently labeled dideoxynucleotide, complementary to the nucleotide in the SNP position, to the SBE primer. SBE reactions can be multiplexed and many SBE products can be analyzed simultaneously by electrophoresis (see Figure 2 for example). In the electropherogram, the length of the SBE primer identifies the SNP locus and the color of the fluorescent label identifies the SNP allele.

For heterozygous individuals, the SBE primers are labeled with two different dyes, and consequently, the extended SBE primers are detected at different wavelengths and appear in different dye windows of the electropherogram. This is exemplified in Figure 2, where the G and A alleles of the SNP locus named A23 (rs826472) appear in the blue and the green dye windows, respectively. The signal strengths of the two alleles are not necessarily equal because the strengths of the fluorophore emissions vary between the fluorophores.

By defining locus-specific rules for data analysis based on the peak height or the peak area, it is possible to introduce a quality gauge on each allele call. The relative signal strengths of the two alleles at a locus are reproducible from experiment to experiment and from sample to sample. Usually, the acceptable peak height ratio of a heterozygous allele call may be defined as $m \pm 40\%$, where m is the mean of observed ratios in approximately 100 unrelated heterozygous individuals. Similarly, the signal-to-noise ratio of homozygous allele calls can be clearly defined. The ratio depends on the fluorophore, but usually a signal-to-noise ratio of 5–20 to 1 is adequate. The rules for data analysis ensure consistency in the data analysis and they simplify training of new analysts. Furthermore, they are important

Figure 2 DNA was extracted from a bone sample. The sample was typed with (a) the AmpF/STR® SEfiler Plus™ PCR amplification kit (Applied Biosystems) and (b) the SNPforID multiplex. Approximately 250 pg DNA was used for the PCRs. Amelogenin and two STR loci (D8S1179 and D19S433) were typed with the STR kit. Allele calls are shown in boxes. No fragment with a 6-FAM™ (blue) or PET® (red) dye was detected. The match probability based on the STR results was 8.1×10^{-3} . A total of 49 SNPs were typed with the SNPforID multiplex. The results from 21 of the 49 SNPs are shown. Allele calls are shown in boxes, for example, 'A21G,' which is the G allele of SNP number A21 (rs722098). 'PU' is a pull-up. The match probability based on the SNP results was 1.2×10^{-21} .

for the evaluation of the sample itself. With STRs, it is usually easy to detect mixtures, simply because more than two alleles will be observed at several loci. With biallelic SNPs, it is not possible to detect more than two alleles and it is not immediately evident whether the typing results originate from one or more individuals. The only method for determining whether the sample is contaminated or contains DNA from more than

one individual is to look at the signal strengths. An individual may have an unusual peak height ratio at a given locus because the signal from one allele is weak. This is typically caused by a mutation in one of the PCR or SBE primer binding sites. However, if the peak height ratio is suspicious at several loci, it is a strong indication that the sample contains DNA from more than one individual. Applying rules for data analysis

makes it possible to readily identify mixtures even in 20:1 ratios.

Currently, there is no software that supports locus-specific rules for data analysis or even comparison of results in different dye windows. Instead, it is necessary to export the data from the analysis programmed and perform the quality gauging in a spreadsheet. Suspicious allele calls can be identified and the electropherogram subsequently reanalyzed with the purpose of deciding whether the suspicious allele calls should be rejected or accepted.

SNP Typing Assays for Human Identification

Several SNP typing assays have been proposed for human identification purposes in the last decade. Two of these assays, the *SNPforID* assay and the assay based on the individual identification SNPs (IISNPs), have the necessary discriminatory power to function as an alternative or supplement to the standard STR investigations performed in modern forensic genetic laboratories. The histories of the two assays are briefly described below.

The *SNPforID* Assay

In 2002, five European forensic laboratories formed the *SNPforID* consortium with support from the European Community. The purpose was to investigate the use of SNPs in forensic genetics. Several assays were developed via this initiative including SNP assays for prediction of ethnic origin (autosomal SNPs) and of paternal (Y chromosome SNPs) and maternal lineages (mitochondrial SNPs). However, the main objective of the consortium was to develop an SNP typing assay with at least 50 SNPs for identification of human individuals. Criteria were defined for the selection of the *SNPforID* SNPs to ensure (1) that the SNPs were highly polymorphic in most human populations (heterozygosity >0.32), (2) that the SNPs were not in linkage disequilibrium, (3) that the SNPs were unlikely to be associated with cellular functions or with STR loci commonly used in forensic genetic investigations, and (4) that all the SNPs could be amplified by PCR in one reaction. A final panel of 52 SNPs was selected. Typing data from populations on all six continents have confirmed that the SNPs are polymorphic in all populations and no evidence of linkage disequilibrium between any of the selected SNPs have been found. The match probabilities calculated from these populations ranged from 10^{-16} to 10^{-21} .

A multiplex PCR was developed that allowed the amplification of all 52 SNPs in one PCR. This ensured that the sensitivity of the assay was very high, and it was demonstrated that all SNPs could be typed in a single reaction using less than 100 pg of DNA, which is the amount of DNA found in 15 human diploid cells. The amplicon lengths ranged from 59 to 115 bp, and 38 of the amplicons were shorter than 100 bp. It was demonstrated in a number of different studies of highly degraded DNA that the *SNPforID* assay was superior to the commercial STR kits. **Figure 2** shows an example of a highly degraded bone sample typed with an STR kit and the *SNPforID* assay. A positive identification of the individual was not possible with the STR kit because fragments longer than 150 bps were not amplified.

In contrast, the calculated match probability based on the *SNPforID* assay provided convincing evidence of identification.

The *SNPforID* assay was tested in interlaboratory exercises within the *SNPforID* consortium and the European DNA Profiling Group. Overall, it seemed relatively easy to introduce the assay in forensic genetic laboratories. However, it was also clear that the best performing laboratories were those with previous experience with the PCR-SBE-CE method and that extensive training in the analysis of the SNP typing results was required. The *SNPforID* assay has been implemented in a few forensic genetic laboratories mainly as a supplementary tool in relationship casework. The usefulness of the *SNPforID* assay has been demonstrated both in typical relationship cases and in cases involving identification of human remains.

Individual Identification SNPs

A group of population geneticists from Yale University in the United States have worked to identify the best possible selection criteria for a panel of IISNPs. Four criteria were defined: (1) high heterozygosity (global average >0.4), (2) low allele frequency variability between populations (global $F_{st} < 0.06$), (3) average match probability comparable to the standard CODIS STR panel, and (4) the SNPs should be essentially unlinked. A total of 92 IISNPs were selected based on the first two criteria, and a subset of 45 SNPs fulfilled all criteria. SNP typing data from 2300 individuals in 44 different populations were generated by singleplex PCR analyses and used to validate the SNP panel. Match probabilities calculated from the 45 unlinked SNPs ranged from 10^{-15} to 10^{-18} .

Recently, 41 of the unlinked IISNPs and three of the other IISNPs were multiplexed by a group from Hebei University in China. The multiplex was highly sensitive and the 44 SNPs could be amplified in one PCR reaction using only 125 pg of DNA. The amplicon lengths ranged from 69 to 125 bp, and 17 of the amplicons were shorter than 100 bp. The performance of the assay was tested on degraded samples, and it was demonstrated that more information could be obtained with the SNP typing assay than with one of the commonly used STR kits.

So far, there is only one report on a multiplexed assay with IISNPs, but it is likely that this assay may be tested by other forensic laboratories or that other combinations of IISNPs are put together in other multiplexes in the future.

Introduction

The movement away from single-locus variable number tandem repeat (VNTR) markers analyzed with restriction fragment length polymorphism (RFLP) enzymes by the forensic DNA community to short tandem repeat (STR) markers was an important decision for forensic DNA testing. Polymerase chain reaction (PCR) amplification of fluorescently labeled DNA primers of STR loci increased sensitivity of the reaction and allowed for testing of lower DNA quantity samples (from micrograms to hundreds of picograms). The introduction of capillary electrophoresis (CE) was also an important technological advance that increased the speed of testing from weeks with VNTR-RFLP markers to hours with STR markers and helped to automate the process by eliminating laborious processes such as gel pouring and manual loading of samples.

The general structure of STR markers is presented in **Figure 1(a)**. The tandem repeating units of most forensic STR markers are comprised of a sequence motif of four (tetra) nucleotide bases (e.g., GATA). The number of tandem repeats at any marker can vary widely in the population. In **Figure 1(a)**, the STR marker on this chromosome has ten tetranucleotide repeats for a total of 40 base pairs (bp). At specific locations upstream and downstream of the tandem repeats are regions where the fluorescently labeled PCR primers (forward, F and reverse, R) hybridize to the DNA template for amplification. The region between the primer hybridization site and the tandem repeats can be referred to as the 'intervening sequence.' In this hypothetical example, assuming the F and R primers are 20 bp each and the intervening sequences upstream and downstream of the core repeat are both 125 bp, the overall size of the fluorescently labeled '10' allele is $(20 + 125 + 40 + 125 + 20) = 330$ bp.

One limitation of STR markers compared to VNTR markers was the need to increase the number of STR markers tested to achieve a high power of discrimination in the population. Forensic 'discrimination' using VNTR markers can be determined with 5–7 markers compared to 13–15 STR markers. For most commercially available STR kits, the goal of the multiplex is to combine several STR markers into one reaction tube to maximize the genetic information in the sample. In a typical multiplex, the markers are arranged in either three or four dye channels, with the size range of the markers in each dye channel falling between 100 and 400 bp.

For most casework samples, the PCR amplification of STR markers is sufficient for linking the perpetrator's profile to the evidence. When samples are highly challenged or degraded, it may be impossible to obtain the full complement of markers in the commercial STR kit. Instead of a full DNA profile, a partial DNA profile is generated which decreases the power of discrimination. For example, if only 5–6 of the 15 possible markers in the PCR amplify, it is possible that several hundreds

of thousands (or even millions) of individuals in the population would fortuitously match the evidence.

Methods to increase the number of alleles in the profile, such as low-template DNA amplification protocols that increase the amount of DNA polymerase and the number of PCR cycles, may be useful strategies to increase the power of discrimination, but these methods require interpretational guidelines that differ from standard procedures. If the DNA is severely degraded (e.g., no DNA fragment is larger than 200 bp), aggressive amplification methods will most likely be unsuccessful for recovering the higher molecular weight markers and the forensic scientist may need to resort to mitochondrial DNA (mtDNA) testing which is laborious, time-consuming, and has a much lower power of discrimination compared to autosomal STR testing.

The Definition of a miniSTR

One strategy to recover genetic information from challenged samples is to amplify the region using a 'miniSTR.' A miniSTR is the amplification of an STR marker using primers that are as close to the repeat motif as possible. In **Figure 1(b)**, the mini-STR forward and reverse primers hybridize immediately adjacent to the repeat motif with no intervening sequences. Assuming that primers are again 20 bp, the size of this labeled PCR amplicon would be $(20 + 40 + 20) = 80$ bp, a reduction of 250 bp compared to the standard primers in the commercial kit. For the example in **Figure 1(a)**, if the DNA templates from the evidence material are all degraded to 200 bp or less, then the conventional primers would fail to amplify as the overall size of the fragment is 330 bp. The miniSTR primers in **Figure 1(b)** would successfully amplify the 10 allele to produce a result. It is important to note that barring any type of genetic variation in the intervening sequences (discussed later), the results from the miniSTR amplification should be identical to the results amplified from the conventional primers. In other words, the same genetic information is retained between the two different primer sets in **Figure 1(a)** and **1(b)**.

Benefits of miniSTRs

MiniSTRs have been demonstrated as useful for recovering genetic information from a wide variety of challenged samples. In one of the first examples of miniSTRs used for typing 48 telogen hairs, redesigned primers for the STR marker TPOX was reduced by 160 bp compared to the commercial kit. The success rate went from 18% with the commercial kit to 77% with the TPOX miniSTR primers, which is a fourfold improvement. The ability to generate autosomal STR markers from shed hairs and hair shafts represents an encouraging development for

Figure 1 An example of amplification of an STR with two different primer sets. (a) With commercially available primers, the 10 GATA repeats (40 bp) are amplified with the 250 bp intervening sequences and the 40 bp primer sequences to produce an overall fragment of 330 bp. (b) With miniSTR primers, the strategy is to move the primers as close to the core repeat as possible. The miniSTR fragment would encompass the 10 GATA repeats (40 bp) and the 40 bp of the two primers to produce an overall fragment of 80 bp.

analyzing an evidentiary material that is often common at crime scenes and is typically analyzed by mtDNA testing, which tends to be less informative than autosomal STR analysis.

Following the mass disaster events of 11 September 2001, Dr. Robert Shaler of the New York Office of the Chief Medical Examiner requested assistance from Dr. John Butler at the National Institute of Standards and Technology to develop miniSTR primers for the US core Combined DNA Index System (CODIS) loci. Previously, Dr. Butler pioneered the development of miniSTRs for a project to rapidly genotype STR markers using matrix-assisted laser desorption/ionization time of flight mass spectrometry.

MiniSTRs were very useful for the identification of the skeletal remains recovered from the World Trade Center. According to a summary of the identification efforts 4 years after the attack, over one-half of the victim identifications (≈ 850) were made with DNA testing, and of those identified, approximately 20% required miniSTRs. In addition to the increased success rates and improved statistical analyses of typing degraded skeletal remains, the International Commission on Missing Persons has used miniSTRs to sort and re-associate the comingled remains from mass graves following the conflicts after the breakup of the former Yugoslavia.

Commercially available kits of miniSTR multiplexes are available for the forensic DNA community and, in addition to the challenged samples of degraded skeletal remains and telogen hairs, miniSTRs have been used to analyze a wide range of typical casework samples under normal conditions and gave robust results with increased genetic information compared to the conventional STR kits. In addition to the miniSTRs developed for the autosomal CODIS markers, miniSTRs have also been developed for analyzing degraded samples using non-CODIS loci, the Y-chromosome, and X-chromosomal STRs.

Given the success of miniSTR markers, the European DNA Profiling Group along with the European Network of Forensic

Science Institutes in 2006 recommended that the next-generation multiplex of STR kits contain miniSTRs in addition to the loci already tested among laboratories in Europe. This decision reflected the need of the forensic DNA laboratory to resolve partial profiles from degraded stains (where miniSTRs are useful) rather than adding more polymorphic loci to increase the statistical power of discrimination for nondegraded casework material.

Limitations of miniSTRs

Multiplexing of Markers

If the goal of generating a miniSTR marker is to make the amplicon as small as possible, then one limitation of miniSTR markers would be the limits of multiplexing. As present CE analyzers utilize four dye channels for STR markers (the fifth dye channel is dedicated to the size standard), this prevents the ability to multiplex more than 6–8 loci under 150 bp. The polymorphic nature of several of the STR loci can also inhibit the ability to multiplex several loci. For example, the vWA locus has an allele spread from 10 to 24 repeats. The size of the vWA miniSTR developed for the World Trade Center identification efforts ranged from 88 to 148 bp, which prohibits the possibility of adding a second miniSTR marker to this dye channel.

The consequence of having several miniSTR multiplexes for generating a DNA profile is that more DNA extract is consumed during testing. For limited, challenged samples, this may prevent any additional testing by consumption of the sample. One method to separate overlapping loci is to add non-nucleotide mobility modifiers to the primer sequences to create space between the markers. For example, if Marker A has an upper size range of 120 bp and Marker B has a lower size range of 115 bp, it would be unwise to place these two markers in the same dye channel as there is the potential that one cannot distinguish the alleles of the two markers. If several mobility

modifiers were added to the primer of Marker B (e.g., each modifier adds 2.5 bp to the amplicon), then ten modifiers would shift the apparent size of the amplicon by 25 bp, which would place the lower size range of Marker B at 140 bp instead of 115 bp. By shifting the overlapping markers away from each other, the ability to multiplex the two markers is now possible. The mobility modifier technology is currently used in one commercially available miniSTR kit.

Concordance Issues

Another limitation of miniSTR markers is the need to establish concordance with the standard STR multiplex kit as some genetic information may actually differ between the two systems. By moving the primer sequence as close to the repeat motif as possible, it may be possible to lose some of the genetic data in the intervening sequence. An example is presented in **Figure 2**. Focusing only on one chromosome, suppose the locus has ten tetranucleotide repeats and primer 'A' is from a commercial kit.

Unbeknownst to the forensic scientist, in the intervening sequence between the forward primer 'A' and the repeat motif is a 4-bp deletion (**Figure 2**). The consequence of this 4-bp deletion is to produce an amplicon with an apparent '9' tetranucleotide repeats (10 repeats minus 4 bp = 9 repeats). Using the conventional STR kit, this amplicon would type as a '9' allele. For the miniSTR primer 'B,' as the forward primer is now flanking the repeat motif, the 4-bp deletion is outside the region of amplification and therefore not detected in the PCR product: the miniSTR primer generates a '10' allele (**Figure 2**). This would create a discordant genotyping result between the commercially STR kit and the miniSTR primers at this locus.

Another potential scenario is that the miniSTR primer for this marker hybridizes within this region where the 4-bp deletion is present (**Figure 2(c)**). In this situation, the PCR

amplification efficiency could be greatly reduced (producing a relatively small peak in the electropherogram) or completely nullified (with no peak present in the electropherogram). The loss of the peak (null allele) in the electropherogram can be problematic during the analysis stage as a true heterozygous genotype (having two peaks) would appear as a homozygous genotype (only one peak) when a null allele occurs.

It is therefore important to conduct concordance testing during the validation of a new miniSTR assay to understand the degree of genetic variation within the intervening sequences of the conventional STR marker. If the genetic variant affects the primer hybridization region of the miniSTR, the commercial company may add an additional 'degenerate' primer to compensate for the mishybridization.

Conclusions

Forensic scientists have occasionally considered the possibility that STRs may be replaced one day with another marker system, potentially SNPs. One major advantage to SNP testing is that the size of the PCR amplicon can be made small, typically less than 100 bp. Given the large investment in DNA databases of STR profiles, it is unlikely that SNPs will replace STRs in the near future. The emergence of miniSTRs has been a beneficial development in recovering genetic information from degraded samples and will continue to be an important tool for the forensic scientist in the future.

Figure 2 The importance of concordance testing with miniSTR primers. Three different PCR primers are tested for this particular marker with 10 repeats (only one chromosome is shown). Upstream of the core repeat is a 4-bp deletion. With the commercially available primer set 'A,' the 10 repeats appear on the electropherogram as a '9' allele as the 4-bp deletion 'removes' one of the 10 repeats. With the miniSTR primer 'B' adjacent to the core repeat, the 4-bp deletion is not detected and the allele would be genotyped as a '10' allele. If the miniSTR forward primer is placed upon the deletion, then no amplification may be possible as the primer sequence wouldn't match the template DNA sequence. In this scenario (no amplification), a 'null' allele is created.

Mixture Interpretation (Interpretation of Mixed DNA Profiles with STRs Only)

BJ Heidebrecht, Maryland State Police, Forensic Sciences Division, Pikesville, MD, USA

Published by Elsevier Ltd.

Glossary

Analytical threshold The rfu value above which a peak can reasonably be declared to be a true allele. Peaks below this rfu value may be true alleles or may be background signals.

Deconvolution The determination of reasonable genetic profiles that could be contributors to a mixed DNA profile based on quantitative peak information and any interpretation assumptions.

Dropout The failure to detect one or more alleles of a contributor at a given genetic locus due to degradation and/or stochastic sampling of low quantities of template DNA.

Indistinguishable from stutter (IFS) A state that exists when the peaks in stutter position from major contributor's alleles are similar in quantitative value to that of alleles of a minor contributor. As such, it would be valid to reason the peak in question as either stutter or a heterozygous pairing with the minor allele.

Minimum expected peak height ratio threshold (MEPHR) The minimum relative ratio of heterozygous alleles in single source samples expected to be seen, as determined by a laboratory. This value may vary based upon the amplification kit, template DNA quantity, thermal cycling parameters, electrokinetic injection parameters, and the use of any post-PCR cleaning procedures utilized.

Mixture ratio The relative ratio, or percentages, of the DNA contributions of multiple individuals to a mixed DNA profile, as determined by the use of quantitative peak information.

Polymerase chain reaction (PCR) Enzymatic process in which a specific region of DNA is replicated exponentially to produce many copies of the template sequence.

Probabilistic genotype interpretation Analysis of genetic data without using analytical, stochastic, or stutter thresholds. Such analysis requires computer-based quantitative interpretation for the analysis of the number of contributors, mixture ratios of the contributors, overall quantity of DNA present, PCR stutter, relative amplification, degraded DNA, dye separation, and background noise. The final determination of this interpretation model is a comparison of which genotypes are more or less likely to be present in the evidential data.

Stochastic threshold The rfu value above which an apparent homozygote can reasonably be declared to be a true homozygote. An apparent homozygote below this rfu value may have dropout of the sister allele to the detected allele.

Unambiguous allele A peak defined by the analyst as a true allele in the mixture; one that is unreasonable to define as an artifact such as stutter or spectral pull-up.

Introduction

Using defined thresholds is common in forensic science, and it is a practical, though not ideal, decision. However, it should be kept in mind that applying such thresholds is somewhat arbitrary as it is based on the degree of confidence one wishes to apply when defining the thresholds, and that there will be cases where true data lie beyond these thresholds. Therefore, the principles listed here, based upon models using defined thresholds, are applicable to the point at which an analyst can come to a 'reasonable' decision regarding the interpretation of the DNA mixture.

The general approach to mixture interpretation should include the following elements:

1. A general overview of the data prior to the examination of any single locus to make determinations of the number of contributors detected, the possibility of determining a ratio of contributors, and to make determinations about the presence of a distinct major contributor(s).
2. Identification of alleles that are below the stochastic threshold and therefore might have dropout at that locus.
3. Identification of alleles that are above the stochastic threshold but may still involve dropout of an associated heterozygous allele.

4. Examination of loci without unambiguous minor alleles to determine whether the minor contributor(s) is reasonable to be considered masked by the major contributor(s), or might be completely unrepresented by the detected alleles
5. Analysis of the mixture for peaks that may be alleles indistinguishable from stutter (IFS).
6. Reevaluation of the contribution to the mixture that is foreign to the intimate contributor for possible dropout and IFS, if performing an interpretation that utilizes the assumption of an individual being intimate to the sample.
7. Attempt to resolve the mixture to single genotype pairs using mixture deconvolution.
8. Comparison with any reference standards that are to be considered probative to the mixture to make a determination of inclusion, exclusion, or inconclusive.

Determining the Number of Contributors

DNA evidence is generally considered to have originated from more than one contributor if three or more unambiguous alleles are present at one or more loci (excepting triallelic loci) and/or the peak height ratios in loci with only two unambiguous alleles are below the laboratory's

minimum expected peak height ratio (MEPHR) threshold (excepting primer site mutations).

Generally, the minimum number of contributors to a mixed sample can be determined based on the locus that exhibits the greatest number of unambiguous alleles. For example, if no more than four alleles are detected per locus, then the analyst can be reasonably confident that the evidence originated from only two contributors. It must be noted, however, that there exists the possibility of a mixture of three contributors containing no more than four alleles at all examined loci. Further examination of the possible genotype combinations and their calculated peak height ratios, as compared to the laboratory's MEPHR threshold, must be undertaken to discount the probability of three or more contributors (Figure 1).

Based upon the number of unambiguous alleles and the varying peak heights of the alleles, it is possible that a reasonable determination as to the number of contributors cannot be made. In such instances, it is appropriate to rely on the locus that exhibits the greatest number of unambiguous alleles to determine a minimum number of contributors present. For example, if a maximum of six alleles are detected in any given locus, then the analyst can be reasonably confident that the evidence originated from at least three contributors.

Determining a Ratio of Contributors

If a reasonable assumption as to the number of contributors can be made, then it may be possible to determine the relative ratio, or percentage, of each of the contributors to the mixture using quantitative peak information. The quantitative intensity, commonly expressed as relative fluorescent units (rfu) of the DNA typing results of a mixture, will generally be proportional to the relative contribution of each contributor to the mixed biological sample. Thus, the rfu values of the detected alleles can be utilized to calculate an approximate ratio of DNA contributions of individuals to the mixture.

If the mixture has been assumed to be comprised of only two contributors, any loci with four unambiguous alleles can be used as a foundation to make a determination of the ratio of the two contributors. Utilizing the assumption that both of the contributors will be heterozygous, all potential genotype combinations can be tested against the laboratory's MEPHR threshold. If more than one genotype pair combination meets the laboratory's MEPHR threshold, the mixture is close to a 1:1 ratio of contributors. If only one genotype pair combination meets the laboratory's MEPHR threshold, the ratio of contributors at this locus can be estimated as being the sum of the rfu values for the two more significant alleles as compared to the sum of the rfu values for the two less significant alleles (Figure 2). The possibility that stutter may be influencing the rfu values of the less significant alleles, skewing the peak height ratio (PHR) of the minor contributor and ratio of contributors, should be considered.

If the mixture has been assumed to comprise only two contributors, any loci with three unambiguous alleles might be used to further refine the determination of the ratio of the two contributors. As it is possible to have one allele dropping out from a two-person mixture when only three alleles are detected, the possibility of dropout must be investigated prior to determining if a three-allele locus is suitable for use in the determination of a ratio of contributors. If one of the alleles is at or below the stochastic threshold, the possibility exists that one allele at this locus may be unrepresented by the detected alleles. Given this possibility, such loci should not be included in the calculations for determining a ratio of contributors. If all alleles are above the stochastic threshold, the possibility that stutter from a significant allele could be causing the minor allele to be reported as above the stochastic threshold should be considered (see below for further discussions regarding stochastic thresholds). If the minor allele is of a similar quantitative value as stutter from a significant allele, this stutter position peak may be IFS (see below for further discussions regarding peaks being IFS) and such loci should not be included in the calculations for determining a ratio of

Figure 1 Determining the number of contributors.

Figure 2 Determining a ratio of contributors in a two person mixture.

contributors, as an accurate determination of the contribution of the lesser contributor cannot be made. If, after taking into account the stochastic threshold and minor alleles being in stutter position and peaks being IFS, it can still be concluded that the three unambiguous alleles are fully representative of the mixed DNA profiles of both contributors, then the genotype combinations may be homozygous/heterozygous (no allele sharing) or may be heterozygous/heterozygous (one shared allele). All such genotype combinations can be tested against the laboratory's MEPHR threshold and the original ratio of contributors as determined by examination of the four-allele loci.

Similar examination of two-allele loci can also be performed with the genotype pairs including the possibility that both alleles may be shared, only one allele may be shared, or both contributors may be homozygous. Additionally, given the fact that only two alleles are detected, the possibility that one contributor may be partially or completely unrepresented by the detected alleles must also be considered when determining if a locus is suitable for use in determining a ratio of contributors.

After a ratio of contributors has been calculated for several loci, the possibility that one of the contributors may be experiencing degradation of their DNA profile must be considered to determine if continuing the analysis using a ratio of contributors will be appropriate. If the low-molecular-weight loci indicate that the ratio of contributors is close to 1:1, but the high-molecular-weight loci indicate that the ratio of contributors is close to 10:1, this would indicate that one of the contributor's DNA is degraded. As such, it may not be appropriate to define a ratio of contributors for the mixture as a whole. The issue would become even more complicated if one contributor is a significant contributor at low-molecular-weight loci, but is the lesser contributor at the high-molecular-weight loci.

While the above information was provided for mixtures comprised of only two contributors, it may be possible to perform similar examinations on mixtures concluded to be comprised of only three contributors.

If the number of contributors to the mixture cannot be reasonably defined, it may still be possible to define a single major contributor, or a mixture of contributors, distinct from a multitude of minor contributors. This separation of major and minor contributor(s) should be based upon a clear distinction between the rfu values of the alleles purported to belong to the major and minor contributors to discount the possibility of allele sharing between minor contributors creating a false major profile. As the number of possible contributors present in the mixture increases, this separation should be even more distinct as the possibility increases that allele sharing could cause a false major profile.

Alleles below the Stochastic Threshold

The purpose of a stochastic threshold is to define a point at which the possibility that a detected allele may be experiencing dropout of its heterozygous sister allele below the analytical threshold must be considered reasonable. Thus, without any additional information regarding a mixture, any loci having alleles with rfu values below the stochastic threshold must be considered as having data that is not fully representative of all contributors to the mixture. With additional information, the analyst can alter this original assumption and potentially define a locus as reasonable to have data that is fully representative of all contributors to the mixture.

If a reasonable decision can be made to determine the number of contributors to a mixture, the number of alleles detected at a locus can be used to reason if dropout should be considered. For example, if the mixture is reasoned to involve only two contributors, and four alleles are detected at a locus, it is reasonable to conclude that both contributors are fully represented, irregardless of the stochastic threshold. Additionally, the laboratory's MEPHR can be utilized to reason if dropout should be considered. For example, if the mixture is reasoned to involve only two contributors, and three alleles are detected at a locus, pairing one of the detected alleles with an undetected sister allele leaves two

alleles as a genotype pair that can then be compared to the MEPHR to determine if this is a reasonable decision.

Alleles above the Stochastic Threshold

Stochastic thresholds are defined based upon a sample being a single source. Issues of shared alleles and the influence of stutter are not considered when examining single source samples. However, when analyzing mixtures, such issues could artificially inflate the rfu value of an allele such that it is detected above the stochastic threshold while it might truly have an undetected sister allele. The analyst's interpretation as to the number of contributors, the ratio of contributors, and the laboratory's MEPHR should be used to examine this issue further. If the analyst cannot reason why stutter or allele sharing is not significantly influencing the rfu value of an allele above the stochastic threshold, then dropout must still be considered a possibility (Figure 3).

Loci without Unambiguous Minor Alleles

Mixtures reasoned to be consisting of only two contributors may show from one to four alleles at any given locus. When there are four detected alleles, it can be assumed that no dropout is occurring. When there are three detected alleles, it can be assumed that one allele may be undetected based upon the above-listed information regarding the stochastic threshold. However, when only one or two alleles are detected, the possibility that one entire genotype may be undetected must be examined.

If the mixture has demonstrated a consistent ratio of contributors across various loci, this information can be used in the interpretation. Loci with high rfu values and a close ratio of contributors are unlikely to be experiencing dropout; allele sharing is a more reasonable assumption. Loci with moderate rfu values and a disparate ratio of contributors are more likely to be experiencing dropout; the ratio of contributors may

suggest that the minor contributor's alleles would be expected to be below the stochastic threshold and, therefore, may not be reliably amplifying (Figure 4).

The laboratory's MEPHR should also be utilized in making the determination that a minor contributor may be experiencing dropout. If the detected alleles meet the laboratory's MEPHR, then it is equally possible that the minor contributor may be sharing allele(s) with the major contributor, or may be experiencing some degree of dropout. However, if the detected alleles do not meet the laboratory's MEPHR, then it is unreasonable to assume that the minor contributor is completely unrepresented by the detected alleles; some degree of allele sharing must be occurring to cause the imbalance in the PHR of the major contributor (Figure 5).

Additionally, the overall rfu value of the minor contributor should be considered. If the rfu values of the minor contributor are below the stochastic threshold at several genetic loci, the possibility of dropout becomes more reasonable. If the rfu values of the minor contributor are significantly above the stochastic threshold, dropout becomes less reasonable; allele sharing is a more reasonable assumption. Degradation of the minor contributor should be considered when using this information as this could skew the interpretation.

The final challenge to loci without unambiguous minor alleles is that one piece of information may indicate that allele sharing is a more reasonable assumption, while another piece of information may indicate that dropout is a more reasonable assumption. Declaring that dropout is a possibility will ultimately be statistically conservative toward a defendant who is fully represented by the detected alleles. However, this decision will then also not exclude certain genotypes as being possible contributors that would be excluded if the conclusion were to be that all contributors are represented by the detected alleles.

While the above information was provided for mixtures comprised of only two contributors, it may be possible to perform similar examinations on mixtures concluded to be comprised of three or more contributors.

Figure 3 Cautions about stutter and allele sharing influences in regards to the stochastic threshold.

Figure 4 Using the ratio of contributors to determine if alleles may be undetected.

Figure 5 Using peak height ratio expectations to determine if alleles may be undetected.

Indistinguishable from Stutter

In mixed source samples, it is possible that the alleles of the minor contributor(s) are in a position one repeat shorter than the major contributor(s). If such an allele also happens to be of an intensity such that the rfu value falls below the stutter expectations for that locus, it is possible that the true composition of the mixture may be misinterpreted. Evidence samples that have minor contributor(s) alleles of similar rfu values to the stutter peaks of the major contributor(s) should be reanalyzed with analysis settings such that stutter thresholds are not applied, while maintaining all other analysis settings. Any new data may then be compared to the other minor peaks of the mixture to categorize the questionable data as stutter or to maintain the designation as IFS.

If the rfu of the peak in question is at or above the laboratory's MEPHR when compared to a single (possibly homozygous) unambiguous minor component allele within that locus, it is possible that this peak in question is either stutter as it meets the expectations of a stutter peak, or a heterozygous allele to the single minor allele as it also meets the expectations of heterozygosity for the minor contributor. As the true amount of stutter that is occurring in this specific amplification and at this specific allelic bin cannot be determined, the true composition of this peak cannot be determined. As such, the peak in question must be designated as IFS.

When performing the calculation to determine if the peak in question meets the laboratory's MEPHR when compared to a minor component allele, it is important to note that the PHR calculation is not the lesser rfu value divided by the greater.

The calculation must be performed as the rfu value of the peak in question divided by the rfu of the unambiguous minor allele. Performing the calculation in this manner may produce a result of greater than 100% and will prevent a PHR calculation that does not meet the MEPHR, but that could be explained by the peak in question having rfu values from both stutter and a minor contributor allele.

If the number of contributors to the mixture can be reasoned, this information can be utilized to discount the determination of IFS and therefore distinguish the peak in question as being solely stutter. If the number of unambiguous alleles present in the mixture is maximized by the number of contributors, the possibility that any peaks in stutter position could be true alleles of the minor contributor(s) could only be explained by the presence of a triallelic individual. As such occurrences are rare, the more reasonable explanation is that the peak in question is solely stutter. If the number of contributors to the mixture cannot be reasoned, it is possible that every peak in stutter position, above the analytical threshold, may be a true heterozygous or homozygous allele of the minor contributor(s).

It must be noted that once a locus has been determined to have the possibility of dropout, further investigation into the possibility of peaks being IFS is irrelevant. The statistics that would be applied to include undetected alleles will also include alleles that may be masked by being in stutter position (Figure 6).

Interpretations That Utilize the Assumption of an Individual Being Intimate to the Sample

It is reasonable to assume that DNA typing results obtained from an intimate sample will contain the DNA of the individual from whom the sample was taken. Based on the assumption of a 'known contributor,' refinements to the interpretation of a

mixture may be made regarding the potential for dropout and peaks being designated as IFS. The assumption of a known contributor is only appropriate when such an assumption is nonprobative to the investigation of the evidence.

Evaluation of IFS in Regard to the Presence of a Known Contributor

Considering that the issue of IFS is solely the province of the minor contributor(s), if the known contributor is consistent with the predominant alleles in the mixture, no refinements to the interpretation of peaks being IFS may be made. However, if the known contributor is consistent with being a minor contributor, the DNA profile of the known contributor can be compared against the ambiguous peaks.

Mixtures with a single minor contributor that is consistent with the known contributor

If declaring an ambiguous peak as a potential true allele of the minor contributor would create a minor contributor profile that is not consistent with the known contributor, this would reject the assumption of the known contributor as being the minor contributor. As such, the ambiguous peak can reasonably be defined as being solely stutter. Prior to such rejection of the designation of IFS, the analyst should be confident that their assumption is reasonable.

Mixtures with a defined number of minor contributors including one that is consistent with the known contributor

If declaring an ambiguous peak as a potential true allele of the minor contributors would create a mixture of minor contributors that exceeds the maximum number of expected alleles, given the presence of the known contributor, this would reject the assumption of the known contributor as being one of the

Figure 6 (a) Examining peaks in stutter position to distinguish as stutter or define as 'indistinguishable from stutter'. (b) Examining a peak as 'indistinguishable from stutter' in regards to the stochastic threshold. (a) Adapted from Gill P et al. (2006) DNA commission of the International Society of Forensic Genetics: Recommendations on the interpretation of mixtures. *Forensic Science International* 160: 90–101, with permission.

minor contributors and/or reject the assumption as to the number of defined minor contributors. As such, the ambiguous peak can reasonably be defined as being solely stutter. Prior to such rejection of the designation of IFS, the analyst should be confident that their assumptions are reasonable.

Evaluation of Dropout in Regard to the Presence of a Known Contributor

Considering that the issue of dropout is associated with DNA profiles with low rfu values, if the known contributor is consistent with robust alleles, no refinements to the interpretation of dropout may be made. However, if the known contributor is consistent with being present at stochastic levels, the DNA profile of the known contributor can be compared against the loci where dropout may be occurring.

Mixtures with a single minor contributor that is consistent with the known contributor

If declaring 'dropout is reasonable in the profile of the minor contributor' would create a minor contributor profile that is not consistent with the known contributor, this would reject the assumption of the known contributor as being the minor contributor. As such, the possibility of dropout can be declared as unreasonable; the profile of the known contributor is fully represented by the detected alleles. Prior to such rejection of the possibility of dropout, the analyst should be confident that their assumption is reasonable.

Mixtures with a defined number of minor contributors including one that is consistent with the known contributor

If declaring 'dropout is reasonable in the minor contributors' would create a mixture of minor contributors that exceeds the maximum number of expected alleles, given the presence of

the known contributor, this would reject the assumption of the known contributor as being one of the minor contributors and/or reject the assumption as to the number of defined minor contributors. As such, the possibility of dropout can be declared as unreasonable; the profiles of the minor contributors are fully represented by the detected alleles. Prior to such rejection of the possibility of dropout, the analyst should be confident that their assumptions are reasonable (Figure 7).

Mixture Deconvolution

Once an evidentiary DNA profile has been interpreted for the number of contributors, the ratio of contributors, the presence of a 'known contributor,' the possibility of dropout, and the presence of IFS, it may be possible to utilize this information to make reasonable determinations as to the genetic profiles of the probable contributors. The concept of mixture deconvolution is to examine all of the different possible genotype combinations that could pair together to create the detected results and then eliminate genotype combinations as unreasonable until only a single genotype combination remains as a reasonable explanation of the evidence.

In order to define a genotype combination as unreasonable, the analyst must first determine what would be considered as reasonable divergences from a perfect model. For example, if an average ratio of contributors across the mixture was determined to be approximately 3:1, would a genotype combination that requires the contributors to be at a 4:1 ratio to produce the evidence be considered reasonable?

Mixture deconvolution works best when the ratio of contributors is close. At a disparate ratio of contributors, it may be impossible to distinguish between allele sharing and imbalanced alleles of a heterozygote that still meet the laboratory's

Figure 7 Use of a known contributor's profile to refine the interpretations of the possibility of dropout and peaks that are 'indistinguishable from stutter'. Adapted from Gill P et al. (2006) DNA commission of the International Society of Forensic Genetics: Recommendations on the interpretation of mixtures. *Forensic Science International* 160: 90–101, with permission.

Table 1 Example for a locus with four alleles, assuming the existence of only two contributors

Allele	RFU						
1	1000						
2	500						
3	980						
4	475						
First contributor				Second contributor			
Genotype	RFU's	PHR (%)	Contribution (%)	Genotype	RFU's	PHR (%)	Contribution (%)
(1,3)	(1000,980)	98	67	(2,4)	(500,475)	95	33
(2,4)	(500,475)	95	33	(1,3)	(1000,980)	98	67
(1,2)	(1000,500)	50	51	(3,4)	(980,475)	48	49
(2,3)	(500,980)	51	50	(1,4)	(1000,475)	48	50
(1,4)	(1000,475)	48	50	(2,3)	(500,980)	51	50
(3,4)	(980,475)	48	49	(1,2)	(1000,500)	50	51

Based upon the laboratory's MEPHR, the most likely combinations would be one contributor having alleles 1 and 3, and the second contributor having alleles 2 and 4.

The total RFU of the contributor of alleles 1 and 3 is $(1000 + 980) = 1980$.

The total RFU of the contributor of alleles 2 and 4 is $(500 + 475) = 975$.

Therefore, the first contributor is donating approximately twice the amount of DNA to the mixture as the second contributor $(1980/975 = 2.03)$.

Example for a locus with two alleles, assuming there are only two contributors, based upon an average ratio of contributors of 2:1

Allele	RFU						
1	749						
2	1414						
First contributor				Second contributor			
Genotype	RFU's	PHR (%)	Contribution (%)	Genotype	RFU's	PHR (%)	Contribution (%)
(2,2)	(707,707)	100	65	(1,1)	(374,374)	100	35
(1,2)	(749,707)	94	67	(2,2)	(353,353)	100	33
(1,1)	(374,374)	100	35	(2,2)	(707,707)	100	65
(2,2)	(565,565)	100	52	(1,2)	(749,282)	38	48
(1,2)	(499,942)	53	67	(1,2)	(249,471)	53	33
(1,2)	(374,1414)	26	83	(1,1)	(187,187)	100	17
(1,1)	(299,299)	100	28	(1,2)	(149,1414)	11	72

Based upon the laboratory's MEPHR, and a comparison to the average ratio of contributors, the most likely combinations would be one contributor being homozygous (2,2) and the second contributor homozygous (1,1). However, it is also reasonable that one contributor may be heterozygous (1,2) and the second contributor homozygous (2,2).

Having both contributors heterozygous (1,2) or having one contributor heterozygous (1,2) and the second contributor homozygous (1,1) may not meet the laboratory's MEPHR and/or may be outside of a reasonable range around the expected ratio of contributors and, therefore, may be unreasonable genotype pair combinations.

Additional genotype combinations that include undetected alleles are not shown in this example but should also be considered during the evaluation.

MEPHR. Mixture deconvolution can also be more useful when one of the contributors can be assumed to be a 'known contributor' as this will further eliminate genotype pairs that would otherwise be considered reasonable without such an assumption (Table 1).

Probative Comparisons

While it may be likely that the DNA profile of a probative reference standard has been generated and analyzed prior to the interpretation of the evidence profile, it must be noted that the interpretation of the mixed DNA profile to this point

has been performed completely independent of any comparison to a probative reference standard. Since it is only alleged as to the presence of the probative individual in the mixed DNA profile, it would be inappropriate to have interpreted the evidence with an assumption of the probative individual being present.

Based upon the comparison of the probative reference standard to the interpreted DNA mixture, one of three conclusions can be made. (1) The mixture contains insufficient information to draw a conclusion as to the sources of the evidence. (2) The mixture contains sufficient information within at least one genetic locus to conclude that the probative individual can be excluded as one of the sources of the

detectable DNA. (3) The mixture contains sufficient information within at least one genetic locus to conclude that there is insufficient information to exclude (i.e., can include) the probative individual as one of the sources of the detectable DNA.

Future Considerations for DNA Mixture Interpretation

What has been discussed here is an interpretation process based upon the use of thresholds. Discussions abound about the appropriateness of such a process as it is based upon yes/no decision points in defining signal detected by the capillary electrophoresis instrument as an allele (analytical threshold) and as a true homozygous profile (stochastic threshold). Since such decision points are based on the degree of confidence one wishes to apply when defining the threshold, a more complete process would include a sliding scale of confidence in the data. A peak at a certain rfu point would not be declared to be uninterpretable, but the confidence in the peak being an allele could be modeled with a probabilistic genotype interpretation. A single allele at a certain rfu point would not be declared to be 100% likely to have dropout of a sister allele, but the confidence in the zygosity of the single allele could be modeled with a probabilistic genotype interpretation. While such calculations may be possible with the use of appropriate software applications, there will still likely be a point at which the evidence contains too many contributors, is too degraded, or

is of too limited quantity to ultimately be useful in the prosecution of a criminal matter.

Low-Template DNA Testing

T Caragine, K Currie, C O'Connor, and ZM Budimlija, Office of Chief Medical Examiner of the City of New York, New York, NY, USA

Published by Elsevier Ltd.

Glossary

Allelic drop-in A stochastic effect due to the amplification of very minor template DNA that is foreign to the main component.

Allelic drop-out A stochastic effect resulting in the absence of an allele from a main component because of extreme heterozygote imbalance.

Frye hearing A judicial procedure in the United States that determines the admissibility of evidence tested with a specific technique based on its general acceptance in the relevant scientific community.

Likelihood ratio The ratio of the probabilities of a set of data under two competing hypotheses.

Low-template DNA testing A more sensitive methodology of performing traditional DNA testing involving a limited quantity (or quality) of DNA, which will exhibit increased stochastic effects.

Primary transfer Standard mode of deposition of biological material from one person to an object.

Random match probability The chance of selecting a random person from a population that will have the same DNA profile as that of the evidentiary sample, showing its rarity.

Secondary transfer Transfer of biological material either from one person to a second person and then to an object that is sampled, or from one person to an object and then to a second person who is sampled directly.

Stochastic effects Random phenomena in DNA analysis such as allelic drop-out, allelic drop-in, heightened heterozygote imbalance, and increased stutter, which result from amplification of nonoptimal amounts of template DNA.

Stutter Slipped-strand mispairing during DNA amplification, which is more prevalent in amplification of repeated regions.

Tertiary transfer Transfer of biological material from a person to an object which is then handled by a second person who touches another object. This object is sampled. Alternatively, material could be transferred from one person to a second person who handles an object, which could then be touched by a third person who is sampled directly.

Validation A set of experiments that test whether procedures meet specifications for their intended use. This testing should be performed on any method before it can be implemented in forensic laboratories.

Definition

Low-template (LT) DNA testing is a more sensitive way of doing traditional DNA testing and refers to the analysis of samples that contain small amounts of DNA such as those with <100 pg of DNA. This technique is sometimes referred to as low copy number (LCN) testing, high-sensitivity (HS) testing, trace DNA, touch DNA, or contact DNA. The amount of DNA recovered from handled samples, wherein skin cells have been deposited, is generally much lower than the amounts recovered from visible biological stains (i.e., blood or semen stains). LT-DNA testing can alternatively be defined as any technique involving a limited quantity (or quality) of DNA, which will exhibit increased stochastic effects. Difficulty lies in attempting to establish a universal threshold below which LT-DNA techniques should always be used as stochastic effects increase with decreasing amounts of template DNA and span a continuous range. Nevertheless, for practical purposes, thresholds are useful in triaging samples. LT-DNA methods use the same laboratory techniques as conventional DNA testing; however, they include slight modifications that are designed to increase the DNA signal.

Applications of LT-DNA Testing

LT-DNA testing is not a new or unique technique to the forensic community and has been used throughout the scientific

community for many years in many different areas. In 1996, French scientists Taberlet et al. described 'reliable genotyping of samples with very low DNA quantities using PCR.' They developed mathematical simulations to evaluate the samples amplified with low amounts of DNA compared to samples with higher amounts. Through biological experiments, they showed concordance between the two models. A year later, Findlay et al. reported using manipulation and isolation of single cells to perform genotyping using short tandem repeat (STR) analysis. They amplified DNA a large majority of the time (91%), obtained full profiles half of the time (50%) and 'usable' profiles (four or more STRs out of six) almost two-thirds of the time (64%).

Low amounts of DNA have been used in many other non-forensic applications including clinical diagnostics, oncology, and immunology. Single-cell polymerase chain reaction (PCR) can be used for preimplantation genetic diagnostics (PGD) to screen for X-linked disorders as well as for sex determination of implanted embryos. Isolation of one fetal cell from maternal blood, in some cases, negates the need for other invasive techniques such as amniocentesis or chorionic villus sampling (CVS), and facilitates treatment of genetic disorders in the early stages of gestation.

In the field of oncology, a single tumor cell variant can be isolated, amplified, and compared to normal, nontumor cells, to identify transcriptional abnormalities. Using reverse transcription PCR (RT-PCR), developmental biologists have examined gene expression patterns during cell differentiation

at the very earliest stages of zygote development. Scientists were able to isolate a single cell and perform PCR to determine the expression pattern and regulation processes of certain genes. British scientist Birgit Liss using RT-PCR studied the gene expression of individual cells of varying types in close proximity in the brain.

More recently, Austrian scientists (using either laser microdissection or micromanipulation techniques) performed whole genome amplification on normal lymphocytes, umbilical cord blood, polar bodies and oocytes, and colorectal, renal, breast, and blood cancer cells. Cells were then screened for chromosomal abnormalities. In 2008, mutational analysis of single cancer cells showed that most of these cells shared a common origin. Furthermore, individual DNA molecules were captured in droplets to allow single copy genetic amplification (SCGA) in a high-throughput manner.

Amplification of low amounts of DNA in forensic casework was first performed in 1999 at the Forensic Science Service (FSS) in Great Britain. As an alternative to mitochondrial DNA analysis, which cannot provide individuality due to matrilineal inheritance (through the mother), lead scientist Dr. Peter Gill and his colleagues built a framework for not only the analysis of lower amounts of DNA but also the interpretation of results obtained from such techniques. This paved the way for these techniques to be employed in crime laboratories throughout Europe, America, Australia, and New Zealand.

Implementation of LT-DNA Testing

In order to detect minute amounts of DNA, the following enhancement techniques are typically used: additional PCR cycles or modifications to PCR, purification of PCR products, and/or increased parameters for electrophoresis. These enhancements exaggerate stochastic effects that are inherent to all DNA testing. Effects include allelic drop-outs and drop-ins, inflated peak imbalance, and/or large stutter artifacts. For example, amplification of very minor template DNA could result in the observance of an allele that is foreign to the main component, otherwise known as an allelic drop-in. For forensic evidence, this DNA may have originated either before or after the commission of a crime. Another consequence is heightened heterozygote imbalance which at its most extreme may lead to the absence of an allele from the main component, or allelic drop-out. Furthermore, if a stutter peak occurs early in PCR, its height will be taller relative to the main peak if additional cycles were used. To accommodate these phenomena, routine testing and interpretation protocols must be modified.

Forensic practitioners employ specific quality control, testing, and interpretation procedures to accommodate stochastic effects. Studies unique to each laboratory must be performed to demonstrate that these strategies generate reliable, robust, and reproducible results. These studies are a validation or a comprehensive test of procedures and interpretation policies used in forensic casework.

Through validation, a laboratory must demonstrate that they are working in an environment that has extremely low levels of background DNA. Overall precautions used in tissue

culture should be employed. For example, testing should be performed in dedicated, protected workspaces in order to prevent inadvertent contamination from laboratory personnel. Proper protective attire should also be worn which consists of full laboratory gowns, face masks that cover one's nose and mouth, gloves (double gloves for bench work and evidence exam), and hair coverings. All equipment must be routinely cleaned, both before and after each procedure and examination of each evidentiary item. One common methodology for cleaning is the use of 10% bleach followed by water and 70% ethanol. Any exogenous DNA in plasticware and water should also be removed either through irradiation with ultraviolet light or ethylene oxide fuming.

To ensure that all reagents and instruments are free of exogenous DNA and function properly, they should be tested prior to use. Moreover, controls must be evaluated with every test including extraction, purification, concentration, amplification, and separation. Positive (optimal) controls show the robustness of the test, whereas negative controls show that the results are acceptable and should be treated in the same or more sensitive manner as actual samples. Owing to the sensitivity of the test, it is not unlikely that some DNA may be detected in negative controls. This DNA is not due to global contamination but is often tube specific. Validation studies must establish how much DNA may be detected in the negative control(s) that would not affect the results in the samples.

Another strategy to identify spurious DNA is through repetition. The extracted DNA is equally divided such that each test contains, for example, up to 100 pg of template. Although the number of repetitions employed may vary from two to four among laboratories, the common theme is that an allele must be seen at least twice to be confirmed. Alleles that do not repeat may not be attributed to a major component. It has been shown that single amplifications are misleading, and that by using this biological model, one can identify alleles that can be attributed to contributors. In addition to replicate analysis, characteristics such as heterozygote imbalance, the amplification efficiency of the loci, and increased stutter are considered when determining genotypes.

In order to confirm that results (even those from the lowest template amount of DNA used) are reproducible, notwithstanding anticipated and explained stochastic effects, LT-DNA procedures should be extensively validated. Studies are conducted with samples wherein the DNA profiles of the contributors are known. These samples should mimic forensic casework and include items from blood, bone, saliva, semen, and skin cells. Validation verifies the protocols used to deconvolute samples to ensure the accuracy of allele assignments in the presence of spurious alleles and increased stutter. Furthermore, validation should determine the precision of the quantitation assay as typically the amount of DNA dictates whether LT-DNA amplification procedures are employed.

Statistical Considerations for LT-DNA Analysis

For a random match probability calculation in LT-DNA analysis, the approach is not different than the one used in high-template (HT-DNA) analysis. This statistic is appropriate only for single-source samples or for deduced profiles from

mixtures. Only those alleles that meet interpretation criteria should be used for the calculation. If one allele is undetermined at a locus, the random match probability can be calculated by using the '2p' rule.

For some mixed samples, the genotypes of one or more individual contributor may not be resolved. Nevertheless, DNA profiles of known samples may be compared to the results, and alleles from all replicates should be considered. If all of the alleles seen in the comparison sample's profile are seen in the mixture, the probability of inclusion can be calculated. This value indicates the number of individuals who could be contributors to the mixture as they have that same combination of alleles.

If an allele seen in a known sample's profile is not seen in the mixture results, this does not necessarily mean an exclusion as there may be scientific explanations for this absence. These include the amount of the template DNA, degradation, the number of contributors to the mixture, the amplification efficiency of the locus in question, and the length of the STR repeat. In order to put a statistical weight on this comparison, more complex calculations are required.

It is well documented that LT-DNA analysis itself is a complex process; hence many different probabilities can be calculated. Ideally, probability models should encompass the likelihood of drop-in and drop-out and should consider the frequency of alleles in unrelated as well as related populations. Likelihood ratios can be calculated for a range of scenarios from a single contributor to multiple contributors where one or more are unknown. Software that integrates allele frequencies and the probability of drop-in and locus specific drop-out for a number of scenarios has been developed and recently validated in a forensic casework laboratory.

A critical factor to the likelihood ratio calculation is the number of contributors to a mixture. Determining this value is challenging without incorporating the frequency of these phenomena in another probabilistic model because of allelic drop-out and drop-in. Nevertheless, models using the maximum likelihood method or empirically based criteria can be used for this estimation until more advanced software is available. Such a probabilistic model that includes all parameters is difficult to achieve; therefore, approximations may be considered given that assumptions are clearly stated.

Casework Examples

LT-DNA analysis has been used in forensic casework for well over a decade and evidence tested with this analysis has been admitted in courts of law in various countries. The technique has been extensively validated in many laboratories and thus has gained general acceptance in the relevant scientific community. The following two seminal court cases highlight this.

'The Queen Versus Sean Hoey' Case (Omagh Bombing)

The Omagh bombing incident was part of a series of bombings and attempted bombings between 1998 and 2001 in Northern Ireland and London, United Kingdom. In the summer of 1998, a car bomb exploded in a busy shopping area in the District of Omagh in Northern Ireland. The explosion killed 29 and

injured hundreds of people, making it the deadliest event in 30 years of violence in Northern Ireland. In 2003, the police arrested and charged an electrician, Sean Hoey.

The prosecution built their case on evidence that they believed to show a connection between the suspect and the bomb fragments found at the crime scene. The evidence was tested in two stages. Initial testing included reconstruction of the bombs and fiber comparisons. The evidence was then reexamined in 2000–01 for DNA, using LT-DNA testing at the FSS. DNA recovered from devices from April 1998 and April 2001 yielded the same profile that matched Sean Hoey. In September 2003, as well as in November 2003, additional matches were made on additional bombing devices. However, all these devices were undetonated, and no DNA was actually detected from the detonated device from the Omagh bombing.

Unfortunately, in 1998, little precaution was taken to maintain the integrity of the evidence. The risk of DNA contamination and cross-contamination among items during the collection of evidence was high. All of these circumstances resulted in the decision of the presiding judge, Judge Weir, to dismiss the DNA evidence stating that "... items had not been collected or preserved using methods designed to ensure the high degree of integrity needed not merely for DNA examination but for the more exacting requirements of LCN DNA." The main arguments against LT-DNA testing were that the technique was not validated by experts outside of the FSS. In his judgment, Judge Weir gave a definition of validation and stated that the LCN system had not been sufficiently validated by the international scientific community. Based on sources from the Crown Prosecution Service (CPS), this case resulted in a temporary 3-week suspension of LT-DNA testing in the United Kingdom, followed by an internal review of current FSS LT-DNA cases. This review was completed and the suspension lifted on 14 January 2008 with the CPS stating that "... it had not seen anything to suggest that any current problems exist with LCN (LT-DNA)." It was stated that there is "... no inherent unreliability in the LCN DNA analysis process. ..."

Queens LT-DNA Frye Hearing

The *Frye* standard or *Frye* test, evaluates whether a technique is generally accepted in the relevant scientific community and thus determines whether evidence tested with this procedure is admissible in a court of law. The first fully completed judgment regarding the use of LT-DNA autosomal testing in the United States is the case of the People of the State of New York versus Hemant Megnath, presided by Judge Robert J. Hanophy of the Supreme Court, Queens County.

The defendant was charged with murder in the first degree for allegedly slashing the victim's throat outside her home. Mr. Megnath allegedly fled in his vehicle that was then the subject of a search warrant. Samples, some of which contained LT amounts of DNA, linked the defendant to the commission of the murder.

In the final ruling, Judge Hanophy stated: "Based upon the testimony presented at this hearing, the court makes the following findings of fact and conclusions of law. ... The court also finds that the credible evidence presented at the hearing established that the OCME validation studies regarding LCN

DNA typing yielded reliable and reproducible results in 100% of the samples tested. The court finds that the OCME has properly developed interpretation protocols for LCN DNA testing based upon its extensive validation studies and that when correctly performed these protocols consistently yield reliable and reproducible results. . . . Therefore, based upon all of the evidence presented to the court during the hearing, the court finds that the People have demonstrated by ample credible evidence that LCN DNA testing with its increased amplification cycles as performed by the New York City OCME clearly passes the standard enunciated in *Frye* and is therefore admissible at trial. . . .”

“Moreover, in addition to holding that the *Frye* standard of reliability has been met in this case, the court also finds that the standard enunciated in *Frye* pertains only to *novel* scientific techniques. In this case, based upon the credible evidence presented at this hearing, the court finds that LCN DNA profiling as conducted by the OCME is *not a novel* scientific technique. . . . DNA testing in the forensic community has been generally accepted as reliable for many years. It has also been found to be admissible under the *Frye* standard in New York courts for over 20 years. (See *People v Wesley*, *supra*.) The analysis that is utilized in HCN DNA testing and which has been admitted nationally in our courts for years is basically the same type of DNA testing that is used when LCN DNA testing is performed by the OCME. . . .”

“Since the LCN DNA method of testing as performed by the OCME is basically the same technique as HCN DNA testing, with the exception of its increased amplification cycles, the court finds that LCN DNA testing as performed by the OCME is not a *novel* scientific technique for the purposes of the *Frye* inquiry. . . . Indeed, both the LCN and HCN forms of DNA testing require the same steps to be taken. These steps, namely extraction, quantitation, amplification, and electrophoresis, are virtually identical in both HCN and LCN DNA testing. Similarly, the same issues such as stutter, allelic drop-out or drop-in occur in both forms of testing as well. In fact, the OCME has prepared and followed interpretation protocols for both HCN and LCN DNA testing to compensate for these scientific phenomena when and if they occur. These protocols were developed by the OCME based upon its validation studies and based upon similar protocols that have been used globally by other forensic scientists who perform HCN and LCN DNA testing. . . .” At trial, all evidence was presented, and the defendant was subsequently found guilty.

Other Case Examples

LT-DNA testing has been used in current casework, cold cases, and post conviction testing, and in a wide variety of case types including homicides, assaults/sexual assaults, property crimes, arsons, hate crimes, missing persons investigations, and the identification of human remains. LT-DNA profiles have been generated from many types of handled evidence including items that have been handled extensively or briefly by an individual(s). These items include cars, airbags, doorknobs, windowsills, tools, jewelry, keys, lighters, matches, letters, envelopes, pens, sides of bottles, weapons, and shrapnel from explosive devices. Fingerprints (both fresh and archived) have

also yielded profiles. Moreover, foreign DNA has been identified on ligatures such as ropes, cords, and tape, as well as on clothing. The exact location where the assailant came in contact with the clothing is helpful to target testing.

Although the main application of LT-DNA testing in criminal casework involves items that were potentially handled or touched, it has also been used on old, degraded, or otherwise compromised body fluid samples. An example of a case where LT-DNA testing was done on one such sample involved the alleged sexual assault of a woman in New York City. In 2005, a woman went out drinking with friends, later separated from her friends and met a group of men. She left with one of the men looking for a party. During that time, she allegedly was raped. When she reunited with her friends, she had a physical altercation with one of them, but the fight was stopped when she declared that she was previously sexually assaulted.

A rape kit was taken, which was negative for semen, but there were bite marks found on the woman’s arm and shoulder; based largely on the testimony of the woman, the accused man was convicted of sexual assault and sentenced to 20 years in prison. He still maintained his innocence and requested examination of the swabs from the bite mark. LT-DNA testing revealed only female DNA and the profile generated was consistent with that of the woman’s friend. The woman subsequently confessed that the sexual assault never occurred, and the conviction was overturned in 2010.

Additional Considerations

The weight of any evidence depends on the context of the case, and DNA is no exception. A DNA analyst may determine the type of body fluid/material that was deposited, the amount of DNA recovered, and the source of the sample. However, the age of a sample and the manner in which it was deposited (either directly or indirectly) are indeterminable. Studies have been performed, nevertheless, to determine how likely DNA can be transferred from one person to another and from people to objects.

The amount of DNA deposited or recovered from an object depends on a number of factors such as whether a person washed their hands prior to handling the object, the number of people who touched the object, how the object was stored after it was handled, and the amount of time prior to testing. The ability of an individual to deposit his/her DNA on an object has been assessed in a study by British scientists Lowe et al., where they evaluated the ‘shedder type’ of an individual based on the ability to detect a DNA profile on an object after it had been handled. If a full profile was able to be obtained, even after hand washing, these people were labeled as ‘good shedders’ as opposed to ‘poor shedders’ where only a partial DNA profile was obtained.

There are several theoretical methods of transfer. Primary transfer is the standard mode of deposition from one person to an object. If a person touches the handle of a knife and then his/her DNA is recovered from that handle, that would be a mode of primary transfer. Secondary transfer refers to either the transfer of DNA from an individual directly to another individual who then handles an object that is sampled or

from a person to an object that is then touched by another person who is swabbed or sampled. For example, person A shakes hands with person B and then person B handles a firearm. Intuitively, one would expect to recover less of person A's DNA than person B's from the firearm. Tertiary transfer involves the transfer of DNA from a person to an object that is then handled by a second person who touches another object. This object is then sampled. Alternatively, DNA could be transferred from one person to a second person who handles an object that could then be touched by a third person who is then sampled directly. For instance, person A touches a doorknob and person B touches the same doorknob and then a knife. The question is whether person A's DNA can be detected on the handle of the knife.

Studies have shown that although DNA from skin cells may be detected through secondary transfer, the extent of this transfer is limited to certain situations. For example, in order to detect the DNA of the first person, the second person had to touch the item immediately following contact with the first person. If any items were handled in between, the DNA of the first person was likely to be deposited on those items. In many cases, the original person could not be associated to the sample. If the DNA of the first person was found, samples were always mixed, and the person was typically a minor contributor.

Regarding tertiary transfer, the introduction of another object in the sequence reduces the chance of detecting the first person. Studies demonstrate that if a random object and nonintimate individuals were used, the first person could not be associated with the sample although a few alleles were seen, which were seen in the profile of the first individual. If any time elapsed between handling of the first and second objects, alleles such as these were not apparent. These studies suggest that it is highly unlikely that a person could be associated to an item through tertiary transfer.

In jurisdictions where LT-DNA analysis is employed in forensic casework, it has proven to be a valuable tool to identify the source of DNA recovered from objects at crime scenes. As with all scientific techniques, laboratories must thoroughly validate LT-DNA protocols to ensure that their individual procedures are reliable and robust. Owing to the possibility of allelic drop-out and drop-in, statistical methodologies for nondeduced mixtures should include the probability of these phenomena. Both qualitative and quantitative results should be carefully considered on the basis of the context of the case. Overall, LT-DNA testing expands the capability of investigations and resolves samples that were previously inconclusive.

X-Chromosome Markers

V Pereira and L Gusmão, IPATIMUP, Porto, Portugal

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Exclusion power Power of a given marker or a set of markers to exclude a random individual of the population from biological paternity.

Genetic drift Random fluctuation of allele frequencies in a locus. The strength of genetic drift is different according to the size of the population: the effect is stronger in small populations. In the long run, genetic drift contributes to loss of genetic variation in a population.

Haplotype Combination of different loci alleles on a chromosome that are transmitted/inherited together.

Likelihood ratio Statistical test that calculates how many more times a certain observation is more likely to occur, comparing two different alternative scenarios.

Linkage disequilibrium Nonrandom association of alleles at two or more loci, located on the same or in different chromosomes.

Power of discrimination Power of a given marker or set of markers to distinguish between two random individuals of a population.

Random match probability Probability that a random DNA sample has the same profile as the DNA sample obtained from the evidence.

Abbreviations

DNA	Deoxyribonucleic acid

LD	Linkage disequilibrium
PAR	Pseudoautosomal region
PD	Power of discrimination
SNP	Single nucleotide polymorphism
STR	Short tandem repeat

The X-Chromosome

Origin and Evolution

The X-chromosome is one of the sex chromosomes in humans. With around 155 million base pairs and 1100 genes, it represents about 5% of the total human genome that comprises 20 000–25 000 genes.

The two sex chromosomes have originated from an ancestral autosomal pair (Figure 1). Around 300 Mya, this pair of autosomes started to accumulate differences and suffered structural and functional changes throughout the evolution, originating two different chromosomes – X and Y.

Even though they have a common origin, the X- and the Y-chromosomes followed different evolutionary paths: the Y-chromosome has lost most of its genomic material and does not suffer recombination in 95% of its extension, while the X-chromosome still retains traces of its autosomal past, suffering recombination along its entire length during female gametogenesis. Homology between the two chromosomes is still present in the telomeric pseudoautosomal regions (PAR 1 and PAR 2; Figure 1).

Characteristics

The particular characteristics of the X-chromosome make it an interesting subject for genetic studies. Many genetic conditions have already been described as being related to mutations in specific genes on the X-chromosome. Hemophilia is a classic

example of an X-chromosome-associated disease, among others.

In the last decade, the interest in the study of the X-chromosome markers as tools for forensic and population genetic studies has been growing, as they can help to detect underlying patterns of genetic differentiation that are not usually captured by the traditionally analyzed autosomal markers.

Humans have one pair of the sex chromosomes, but the number of X-chromosomes present in each cell varies between males and females. Females have two copies, while males have one X-chromosome and one Y-chromosome. Therefore men inherit their X-chromosome from their mothers, whereas women inherit one X-chromosome from each parent (Figure 2). The paternal X-chromosome they receive does not suffer recombination (except in the PARs) and is transmitted directly to the daughters. The maternal X-chromosome contains combined information from the two X-chromosomes present in the mother.

Given the difference in copy number in males and females, the study of the X-chromosome in men allows direct access to their haplotypes. As recombination only occurs in females, in each generation, only two-thirds of X-chromosomes recombine. The X-chromosome is thus disproportionately influenced by female demography, making the study of the X-chromosome particularly useful for detecting subtle differences between the two genders.

In a population with equal number of female and male individuals, there will only be three X-chromosomes for every

Figure 1 Evolution of the sex chromosomes.

Figure 2 Genetic transmission of X- and Y-chromosomes.

four autosomes present. Furthermore, for each three X-chromosomes in a population, one will be paternally and two maternally inherited. This will lead to clear differences not only in the recombination but also in the mutation rates between the two, as in the X-chromosome the rates will be lower due to the higher mutation rate in male gametogenesis.

Owing to these characteristics, and also due to its younger age, the diversity on the X-chromosome is expected to be lower than on the autosomes. As a consequence, and looking at it from a population genetic point of view, the effects of selection, genetic drift or substructure in a given population are more pronounced. The same is observed in the linkage

disequilibrium (LD) patterns. LD can be defined as the non-random association of alleles at two or more loci. Several factors are responsible for breaking the extent of LD in a chromosome, such as the physical distance between the markers and recombination and mutation rates. Given that recombination only occurs in females, only one half of the X-chromosomes in a population will recombine in each generation, and therefore it will necessarily take more time to break down LD by recombination. As a result, LD is greater when compared to the autosomes and the size of regions with a single genetic history is larger, making it a better and more accurate tool to detect patterns of LD in populations.

The comparative analysis between the autosomes and the X-chromosome can also be used to reveal differences in demographic histories, migration, and breeding patterns of females and males. The usual studies of gender-biased demographic events compare information obtained from the Y-chromosome and mitochondrial deoxyribonucleic acid (mtDNA) markers. Unlike mtDNA and Y-chromosome analyses that inform about the history of female or male lineages respectively, the X-chromosome allows the simultaneous study on both genders, making it an ideal system for studying population genetic differences between males and females regarding mutation rates and patterns of recombination. Owing to recombination, the X-chromosome is composed by a block-like pattern with different chromosomal regions being informative of distinct genetic histories, unlike uniparental markers that are transmitted as a single locus and where all the markers share the same genealogic history.

X-Chromosome Markers in Forensic Genetics

As previously mentioned, the X-chromosome combines some of the desirable features of autosomes and uniparental markers (Y-chromosome and mtDNA) and its particular characteristics make it an important tool in population and forensic genetic studies.

Forensic genetics is largely based on population genetic studies. The presentation of forensic genetic evidence in court is done in the face of uncertainty, with likelihood ratios that statistically compare, the probabilities of a certain observation under two alternative hypotheses with the random population serving as background.

The bulk of forensic genetic casework is related to three main areas: analysis of trace samples, individual identification, and establishment of biological relationships in paternity testing or other kinship analysis.

The following section presents some of the situations where the use of the X-chromosome markers can answer some of the challenges that cannot be solved by any other kind of genetic marker, and situations where it can serve as a complement of autosomal data analysis.

Analysis of Trace Samples

Autosomal markers are the method of choice for trace and stain analyses in forensic routine casework. They can give a reliable answer in most of the situations because of the high power of discrimination (PD) of the currently available kits.

The utility of X-chromosome markers in the analysis of trace samples and the PD of such markers varies, depending not only on the sex of the individual but also on the nature of the trace/mixture.

If female traces are to be searched in a female background (female epithelial cells under a woman's finger nails, for instance), then the information given by the X-chromosome yields the same results as autosome analysis, with no gain in the PD.

When male traces ought to be searched on male background, the use of X-chromosome markers is not advisable, as with only one X-chromosome to be analyzed, only one allele by locus will be used and, therefore, the PD value will be lower.

In mixed samples where a female and male individual are being investigated, the advantage of using the X-chromosome occurs in situations where there is a female trace to be identified in a male background contamination. In this case, the PD of the X markers will be higher than the autosomes. The probability of having all the female alleles included in the male profile means that the female has to be homozygous for all the systems considered, which has a low probability of occurrence for forensic selected markers with high diversity.

As mentioned previously, in situations where a male profile is searched in a female background, it is not advisable to use the X-chromosome, as the probability of the male profile being included within the female alleles is high.

As a last remark, X-chromosome analysis can also be useful in traces collected from old and degraded samples, where most of the autosomal data may be missing. It can also be used in individual identification in victims of mass disasters, where limited amounts of DNA are available and family relationships must be established on the basis of few genetic markers.

Paternity Cases and Kinship Testing

As for the trace samples, most of the routine casework presented to forensic practitioners regarding paternity cases involving trio constellations can be easily solved with autosomal markers.

The use of the X-chromosome can be very efficient and give additional information in father-daughter or mother-son relationships.

Owing to its mode of inheritance, the analysis of X markers on father-son relationships has no use whatsoever. On the other hand, in a situation where the two alleged fathers are father and son, the analysis of the X-chromosome can be more helpful than the autosomes as they will not share identical X-chromosome alleles by descent.

Female individuals that have the same father will share the same paternal X-chromosome. X-chromosome markers can then resolve relationships involving two sisters or half-sisters, helping to consider or exclude paternity more efficiently than autosomes.

Genealogical and pedigree reconstruction over several generations is also one of the potential applications of the X-chromosome markers, as long as the X-chromosome lineages are not interrupted by father-son relationships.

The main field where the study of X-chromosome markers can contribute the most is in paternity cases where the putative

father is not immediately available and his closest relatives must be analyzed instead. The power of exclusion of autosomal markers decreases, and in this situation, the analysis of X-chromosome markers can be more informative, especially if the putative paternal grandmother is available for genotyping. As males will inherit their X-chromosome from the mother, the putative father's haplotype (that he will then pass to his daughter) can be inferred from the paternal grandmother.

As an example, a case is presented where the access to the putative paternal grandmother can be more informative (Figure 3). In the absence of the putative paternal grandfather (I), autosomal short tandem repeats (STRs) can be insufficient, although uncles V and VI are available. Even in their absence, the analysis of X-STRs from the grandmother (II) is enough to resolve the kinship and determine whether IV and VII are related, as II contains all the alleles present in the putative father, IV.

In more common situations, where there is no information available from the grandparents, the profile from the paternal grandmother can be reconstructed using V and VI. The analysis will be more informative, as more sons/daughters are used to reconstruct the complete profile from II.

Even though the study of the X-chromosome for population and forensic genetics is still very recent compared to the currently established autosomal protocols, the described situations confirm the potential of using the X-chromosome markers in forensic genetics, and their importance in resolving some of the challenges that could not be answered otherwise. From individual identification to paternity testing and kinship analysis, the X-chromosome has proven to be an important and valuable tool.

Different types of markers have been identified along the X-chromosome specific portion, which are now available for multiple applications. Depending on the aim, markers that are more or less apart from each other, showing different degrees of association and presenting varied population diversity levels (usually related with mutation rates) can be selected.

Genetic Markers

Variation among individuals is the core of all forensic and population genetic studies. From its early days, genetic analysis has come a long way since its first approach with the 'classical markers.' Early population and human identification studies

Figure 3 Example of a case where the data from the X-chromosome were more informative than the autosomal data.

were done using the blood-type information of individuals, or with protein and enzymatic markers. The development of molecular biology, and more importantly the development of polymerase chain reaction in 1983, was responsible for a shift in the original focus of the studies, to a new generation of 'molecular markers' where DNA polymorphisms assume a position of prominence.

DNA polymorphisms are usually defined as naturally occurring changes in the DNA sequence among individuals where at least two alleles have a frequency of more than 1% in the population.

Restriction fragment length polymorphisms were the first to be used in human identification studies, but in the last decades, the development and miniaturization of new technologies has made it possible to study other kinds of genetic markers, such as microsatellites or STRs, single nucleotide polymorphisms (SNPs), and insertion/deletion markers (Indels) among others.

Owing to their specific characteristics, different information can be extracted from the different types of markers and it is important that one assesses their adequacy according to the goal of the study.

This article presents a brief review of the characteristics of the most commonly used genetic markers, in the light of their current application to the X-chromosome.

Short Tandem Repeats

STRs are DNA sequences composed by small tandem repetitions (usually from 2 up to 6 bps) whose number varies between individuals.

It is estimated that STRs occur every 10 000 nucleotides, representing around 3% of the total human genome variation. Even though they are spread throughout the genome, the majority of STRs are located in noncoding regions. These markers are selectively neutral and highly polymorphic (with average mutations rates around 2.1×10^{-3}) which renders them a high PD. They can also be genotyped using simple and fast typing techniques.

STRs can be divided into simple or complex, according to the repetitive motive they present. The complexity of the motive and its size has repercussions on the mutation rates and the number of different alleles. Several studies showed that an increase in the length also translates into an increase of point mutations that split the initial motive into smaller ones, and this can be understood as an evolutionary mechanism to control the average size of the fragment.

For all the characteristics already mentioned, the analysis of STRs has become the method of election when assessing genetic diversity in populations.

Although a vast number of STR loci have been described for autosomes and the Y-chromosome in mammals in general, and particularly in humans, just very recently has science focused on the potential of X-chromosome study.

Several human X-chromosome STR multiplexes have been described. A multiplex consisting of ten markers has been developed as a result of a collaborative work carried out by the Spanish and Portuguese Speaking Working Group of the ISFG (GHEP-ISFG).

Commercial kits are also available. The one currently in use amplifies 12 markers simultaneously, plus amelogenin for gender determination (Figure 4).

There is an increase in the publication of data concerning X-STRs, but further studies are still needed on allele frequency distributions, mutation rates, and LD, in order to continue to establish reference population databases.

Single Nucleotide Polymorphisms

SNPs are single base substitutions that are present in the genome. The majority of SNPs is biallelic, but tri-allelic and tetra-allelic SNPs have also been reported.

The advantages of using SNPs in forensic casework and population genetic studies lie in their abundance in the genome – approximately 85% of the human genetic variation can be attributed to SNPs.

Compared to STRs, these markers have lower mutation rates (approximately 2×10^{-8}), and are thus more stable, making them more suitable to use in kinship analyses and in circumstances where pedigree/lineage reconstruction is needed.

SNPs can also be amplified in short fragments of around 60–80 bps. This makes them very useful in old samples with low-quantity DNA template, and/or in degraded samples where the available DNA is fragmented. In these situations, the analysis of SNPs is more likely to produce better results than STR genotyping.

The fact that most SNPs are biallelic decreases their informativity per locus when compared to the STRs (~10–13 SNPs are necessary to get the same discrimination power as an STR). Even though ultimately SNPs will not replace the currently used STRs, they can be used as a complementary tool, increasing the information available.

Depending on the characteristics, location in the genome and the genetic diversity of a certain SNP within and among populations, SNP analysis can be used in individual identification, phenotypic inference, and ancestry or lineage studies.

The International HapMap project is one of the most important studies that report common genetic variants that occur in different human populations. Already in phase III, the

HapMap database has contributed to increase the density of known SNPs across the human genome, and has reported over 10 million nonredundant SNPs to date. The SNP database from the National Center for Biotechnology Information (dbSNP; www.ncbi.nlm.nih.gov/) currently includes over 400 000 X-chromosome-specific SNPs that have been validated and are available for multiple applications.

At the present time, few data on the use of X-chromosome SNP in forensic analysis have been published, although some studies have already shown their applicability in relationship testing and population characterization. This area will have a substantial growth in the upcoming years, as more automated and rapid SNP typing methodologies are developed.

Insertion/Deletion Polymorphisms

Another kind of genetic variation that has gained importance over the last few years is insertion/deletion polymorphisms or Indels.

As the name suggests, Indels are length polymorphisms created by insertions or deletions of nucleotides in the genome. They can be divided into those with multiple alleles or diallelic. Regarding diallelic Indels, their fragment size can vary from one base pair insertion/deletion up to hundreds of kilobase pairs, although the largest group of diallelic Indels varies between 3 and 15 bps.

After SNPs, Indels are reported as the most abundant DNA polymorphisms. Initial studies focusing on the mapping of Indel variation in humans showed that Indel markers represent between 16 and 25% of all sequence polymorphisms in humans. Having in mind that the current number of SNPs reported in dbSNP database is around 10 000 000 and increasing, it is estimated that the human genome might contain around 1.6–2.5 million unique Indel polymorphisms that occur with an average density of one every 7200 bps. Considering the size of the chromosome, the density of Indels reported for the X-chromosome is somewhat lower than the autosomal average; but if one takes into account the amount of information available for each chromosome, however, the

Figure 4 Electropherogram showing the genetic profile of a male individual analyzed for 12 X-chromosome STRs plus amelogenin.

values are similar to the average in the autosomes, representing around one polymorphic Indel every 5–13 kbps.

Even though Indel polymorphisms are quite abundant throughout the genome, just very recently the scientific community has devoted some attention to this particular kind of markers.

The advantage of using Indels in population and human identification studies lies in the fact that they combine many of the desirable features of SNPs and STRs. Their application in these fields ranges from individual identification to population characterization. Like SNPs, they are very commonly distributed in the genome and the majority of them is unlikely to present recurrent mutations. Most Indels have originated from a single mutational event that occurred at low frequency and was subsequently stable. Also like SNPs, the amplification of short fragment Indels can be done in smaller amplicons than those of STRs, improving the chances of having good quality profiles in old and degraded samples, where STR genotyping is unlikely to succeed.

The allelic frequencies of some Indels present clear differences between the major population groups making these Indels useful as ancestry informative markers.

Like STRs, the genotyping of short fragment Indels is relatively easy and fast and can be performed using the already developed methodologies available for STR typing, without the need to use direct sequencing methods or other additional requirements. They are suitable for analysis with

high-throughput technologies and automation of the genotyping systems.

Several studies have reported multiplexes of X-chromosome Indels that contain from 13 up to 33 markers (**Figure 5**). Data is starting to become available for European, African, Asian, and Native American populations, showing the potential of these markers for population characterization and human admixture studies.

Haploblocks

As previously stated, although SNPs are abundant throughout the genome, the analysis of SNPs still has not surpassed STR genotyping due to their lower PD per locus.

Several studies have shown that the human genome has a block-type structure, where recombination hotspots alternate with regions with strong LD. With the detection of this block-like pattern throughout the genome, a new kind of markers has become of potential forensic interest, the haploblocks.

The concept is that several neighboring and tightly linked SNPs will form a block that will be inherited together, and where little or no recombination occurs between them. Even though the PD of each SNP within the block is low, when considered together as a unit, this set of linked SNPs will form haplotypes. As a result, the discriminating power will increase and in theory, it will be equivalent to an STR. The observed haplotypes will be then comparable to alleles in STR loci.

Figure 5 Electropherogram of a male individual genotyped for 33 X-chromosome Indels.

Some studies have already described haploblocks throughout the autosomes, but there is still some work to be done on the X-chromosome. Because of its size, it is expected that four or five blocks could be used for forensic casework.

Conclusions

In genetic identification, beyond the simplest cases of paternity testing and the comparison of genetic profiles from biological samples, situations often arise where the genetic profiles are not complete or where the interpretation of results can be quite complex.

In these situations, combining markers with specific characteristics as well as several regions of the genome with different modes of transmission (autosomes, mtDNA, Y-chromosome, and X-chromosome) has revealed to be successful. Several studies have already shown the usefulness of lineage markers in individual identification in diverse scenarios. X-chromosome markers have also proven their applicability in kinship testing, in situations where autosomal data cannot exclude a certain relationship between the individuals, and therefore do not provide a clear answer.

Given all the interesting features of the X-chromosome that have been constantly highlighted throughout this article, the application of X-chromosome markers in forensic genetics can serve as an additional research tool that can be important to unravel some of the challenges presented in this area.

This article is a revision of the previous edition article by T. Melton and G. Sensabaugh, volume 2, pp. 499–503, © 2000, Elsevier Ltd.

Glossary

Control region The mitochondrial control region (CR) is the single, larger, noncoding portion of the mitochondrial genome. It extends 1122 bp from nucleotide position 16024–576 (relative to the rCRS). Owing to the decreased evolutionary pressure mutations accumulate more rapidly there, which is why the CR represents the most discriminative region in the mtDNA and is primarily targeted for forensic purposes.

Haplogroup Haplogroups are clusters of similar haplotypes that share a common ancestor. mtDNA haplogroups are named using letters and numbers in alternating order, for example H1b, and are characterized by signature mutations through which they are related. For H1b, the signature pattern is 16189C 16356C 16362C 263G 315.1C (relative to the rCRS in the control region). See Phylotree for a curated archive of mitochondrial haplogroup names and mutations.

Haplotype A haplotype is composed of genetic markers (sequences or single nucleotide positions) that are inherited together and do not undergo recombination. mtDNA haplotypes usually consist of sequence segments of the control region and in some cases contain single nucleotide information from the coding region. mtDNA haplotypes are usually reported relative to the rCRS.

Mutation In general, mutations are sudden and spontaneous changes in genomic sequences. It has become practice to call differences between two sequences as mutations. In that way, differences of an mtDNA haplotype with respect to the rCRS are sometimes also referred to as mutations, which is not true, when the sequences are only distantly related to the rCRS and thus, they are not directly linked by mutations.

Phylogeny Phylogeny describes the evolutionary relatedness of organisms/individuals. Owing to its maternal mode of inheritance mtDNA is inherited along a phylogeny. The relatedness between individuals is effectively displayed in trees and networks.

Quasi-median network Here, a quasi-median network (QMN) is a graphical representation of tabular mtDNA haplotypes that can be used to depict intraspecific phylogenies. QMNs have proven useful for pinpointing data idiosyncracies and are therefore used for a posteriori quality control of mtDNA haplotypes.

Revised Cambridge Reference Sequence (rCRS) The rCRS is the corrected version of the first sequenced human mtDNA. It represents the standard reference sequence to which mtDNA sequences are reported as haplotypes. The rCRS can be found on GenBank under accession number NC_012920.

Structure and Basics

Mitochondria are organelles with a superior function in the physiological energy household of the cell. They are the only cell particles in animals to harbor extrachromosomal DNA in the form of mitochondrial DNA (mtDNA), which differs in size, structure, and genetics from the DNA in the nucleus. mtDNA is organized in ringlike structures that are present in the mitochondria as supercoiled double-stranded molecules with an 'external' purine-rich H (heavy) and an 'internal' pyrimidine-rich L (light) strand. It is usually observed that H-strand-derived sequence raw data (generated with reverse sequencing primers) tend to display higher background noise and are often more difficult to sequence than forward L-strand sequences, which plays an important role in the forensic context, as discussed below.

The structure of mtDNA was determined in the late 1960s, with the first human sequence published in 1981. Twelve years later, this sequence was corrected at 11 positions and has since been referred to as the revised Cambridge Reference Sequence (rCRS). The rCRS contains 16 568 bp, which are numbered from nucleotide position (ntp) 1 within the control region (CR) to ntp 16569 in a clockwise manner. This numbering

derives from the earlier version of the first sequence where one base was mistakenly introduced between ntps 3106 and 3107. In order to avoid confusion with already generated data, the rCRS was corrected by introducing an N-designation at ntp 3107, which is why every other sequence differs by a 3107del to the rCRS. Instead of reporting the entire string of nucleotides, the scientific community has agreed to call human mtDNA sequences relative to the rCRS for better legibility with the specification of the reading frame (terminal points of the sequenced fragment excluding primer). A reader then knows that, for example, 16069T 16126C (16024–16365) describes a sequence, which harbors a T at ntp 16069 and a C at ntp 16126 among otherwise identical nucleotides within the range of ntps 16024 and 16365 relative to the rCRS. This practicable annotation is also known as mtDNA haplotype or mtDNA profile and finds its way into mtDNA reports and databases. Since the precise point of insertions and deletions (in terms of their origin from an evolutionary perspective) cannot be unambiguously determined in a consecutive sequence of identical bases, more than one rCRS-coded alignment is possible. In the forensic setting, this may have an impact on reporting and database-querying issues (see the section '[mtDNA Alignment – Phylogenetic Perspectives](#)').

The mitochondrial genome (mtGenome) includes 37 genes that are densely packed in the coding region (577–16023), whereas the CR (16024–576) represents the single major non-coding part of the mtDNA (Figure 1). The latter spans over a range of 1122 bp and includes the vast majority of polymorphic positions owing to a reduced evolutionary pressure. Early sequence studies used the two so-called hypervariable segments HVS-I (16024–16365) and HVS-II (73–340) that have been targeted for population studies and the analysis of forensic samples. It is discussed later that this separate amplification and sequencing analysis harbors the inherent problem of sample mix-up of hypervariable segments between samples in addition to the decreased discrimination power compared to the analysis of the entire CR. HVS-I and -II analysis is therefore no longer state of the art and should be replaced by the analysis of the entire CR.

Biology and Genetics

In contrast to chromosomal DNA, which is present as two parental copies in the nucleus, a cell contains up to multiple thousand copies of mtDNA. According to the endosymbiotic theory, mitochondria derive from arche bacteria, which built a structural and functional association with the cell. Some of the features of the mitochondrial molecule are remnants of this

past, such as the independent replication to the nuclear DNA (nDNA) and the deviating translation code. However, extensive transfer of mtDNA into the nucleus has occurred throughout evolution and is still ongoing, which becomes evident in the form of so-called *numts* (nuclear elements of mtDNA).

Human mtDNA is believed to be inherited solely via the maternal lineage, although paternal leakage and a doubly uniparental mode of transmission are established in some animal species. There are at least two mechanisms by which the inheritance of paternal mtDNA is prevented in humans. First, mitochondria in the sperm cell are outnumbered by those in the egg by at least three orders of magnitude (50–100 in sperms vs. 100000–200000 in the oocyte). Second, in mammals, sperm mitochondria are tagged by ubiquitin which leads to proteolytic digestion in early embryonic development. It has been suggested that the exclusively uniparental pathway has evolved to both mitigate lethal intermitochondrial gene conflicts and prevent the inheritance of sperm mtDNA damaged by free radicals. The analysis of large pedigrees and mother–child pairs has thus far confirmed the maternal mode of inheritance; and while both paternal leakage and recombination of human mtDNA have been proposed, the underlying data and/or methods applied in most of these studies have been challenged. However, in a single yet unrefuted study of a male patient suffering myopathy, paternal transmission of mtDNA was observed. The muscle tissue of the patient showed a

Figure 1 Scheme of the mtDNA control region with three different amplification and sequencing strategies that are applied depending to the degradation state of the available mtDNA. All three strategies lead to consensus sequences with fully double-stranded coverage. Primer designations refer to the three prime ends, primer sequences can be found in the references below. Reproduced from [Eichmann C and Parson W \(2007\)](#) Molecular characterization of the canine mitochondrial DNA control region for forensic applications. *International Journal of Legal Medicine* 121: 411–416; [Parson W and Bandelt HJ \(2007\)](#) Extended guidelines for mtDNA typing of population data in forensic science. *Forensic Science International: Genetics* 1: 13–19. [Berger C and Parson W \(2009\)](#) Mini-midi-mito: Adapting the amplification and sequencing strategy of mtDNA to the degradation state of crime scene samples. *Forensic Science International: Genetics* 3: 149–153.

mixture of the mtDNA of both parents. The paternal contribution differed from the mtDNA of the father by a 2 bp deletion, which was associated with the disease. Other tissues of the patient as well as tissues of other family members did not show the paternal haplotype.

Assuming that paternal leakage may still represent the very rare exception in mtDNA transmission, the observed variation in human mtDNA can only be explained by *de novo* mutations in germline cells that eventually become fixed within descendent individuals through the action of an intergenerational genetic bottleneck. Genuine mixtures of mtDNA molecules within single individuals have been described for humans and are known as heteroplasmy. For instance, the observation of point (sequence) heteroplasmy at ntp 16169 in the otherwise identical sequences of the putative remains of Tsar Nicholas II and those of his brother Georgij Romanov substantiated maternal relatedness and supported the identification of the remains of the Romanov family ([Figure 2](#)). In medical genetics, point heteroplasmy plays an important role in the diagnosis of mitochondrial-based diseases because pathogenic mutations are rarely present in homoplasmic form. Rather they must exceed a critical threshold in the mixture with the wild-type allele before a disease phenotype develops. It has recently been established that nonpathogenic point mutation mtDNA heteroplasmy is common. Extensive CR sequencing analyses of more than 5000 population samples showed heteroplasmy in 6% of individuals, but with the vast majority displaying the mixture exclusively at single sites ([Table 1](#)). Only very few sequences featured point heteroplasmy at two or three positions (0.14 and 0.02%, respectively) and cloning analysis showed that in all of these cases, the constituent haplotypes (three or four molecules, respectively) differed from one another at a single position only. Also, there was a clear tendency for heteroplasmy to occur at known evolutionary hotspots, for example,

at ntps 16093, 152, 146, and 204 with exceptions only at positions 214 and 215. Heteroplasmy, when encountered in forensic samples, requires special attention for interpretation and evidence reporting (see the section 'Practical Aspects of Forensic mtDNA Testing').

The Role of the Phylogeny in Forensic mtDNA Testing

Basics of the mtDNA Phylogeny

The maternal mode of mtDNA inheritance determines the evolution of the molecule along a phylogeny. Mutations accumulated along the radiating lineages of the human phylogeny and left footprints that are still visible and discernible on a subcontinental scale today. Haplotypes that share specific mutations are clustered in haplogroups (hg) that are named with an alternating order of letters and numbers in descending hierarchical order. They can display discrete geographic distributions, such as, for example, hg U5b3. This haplogroup is determined by the CR mutations 228A and 16304C on top of the U5-specific motif 73G 263G 315.1C 16192T, and 16270T. While hg U5 is typical for populations from western Eurasia and can be found at appreciable frequencies from Europe to Central Asia, hg U5b3 is primarily observed on the island of Sardinia, with spurious traces around the Mediterranean coast ([Figure 3](#)). This type of phylogeographic information can be useful in the forensic context when the geographic origin of an unknown sample is under investigation. However, it is important to keep in mind that these forms of phylogeographic inference pertain to the mtDNA lineage, and not the sample or individual specifically. Likewise, inferences of biogeographic ancestry based on the abundance of uniparental lineages are not

Figure 2 Photos and corresponding sequence raw data of a calcaneus fragment (above) and a partial tooth (below) of Tsar Nicholas II. Point heteroplasmy at ntp 16169. necessarily linked to visible phenotypes, as is sometimes mistakenly perceived.

Error Rates in Forensic mtDNA Testing – The Role of the Phylogeny

The developments in mtDNA quality control in the past decade have shown that the phylogeny plays an important role in the discovery of sequencing and transcription errors in mtDNA data. There was increasing evidence in the early 2000s that mtDNA datasets in forensic, medical, and population genetics harbored ambiguous data. This, in turn, led to high profile discussions about the credibility of published mtDNA data in general and their application in forensic testing in particular. Recent developments in the field of next generation sequencing technologies demonstrate that the problems are not limited to the era of Sanger sequencing, but continue to surface also with the introduction of new sequencing technologies. There is no other genetic marker in forensics in which errors become so highly visible. This is due to the fact that mtDNA evolution – characterized by lacking recombination and relatively low mutation rates (compared to short tandem repeats (STRs)) – portrays distinctive sequence patterns. Errors result in haplotypes that stand out.

In an effort to assess how common mtDNA sequencing errors occurred, the forensic community initiated proficiency tests in which a relatively small number of blind samples were analyzed in ring tests. Those experiments revealed an alarming error rate of up to 30% of wrongly reported mtDNA haplotypes. The main causes were transcription errors, phantom mutations, and artificial recombination. Transcription errors include reference bias (fallback to the reference sequence, e.g.,

Figure 3 Spatial frequency distribution of mtDNA haplogroup U5b3 and geographical locations of populations surveyed. Reproduced from Pala et al. (2010) *American Journal of Human Genetics* 84: 1–8, with permission.

152T instead of 152C), transposed digits (e.g., 16039 instead of 16093), base mis-scoring (e.g., 152A instead of 152C), and base shift (e.g., 16279 instead of 16278). Phantom mutations comprise all sorts of artifacts that are associated with the laboratory process and lead to ambiguous base calls in sequence raw lane data such as, for example, signals due to unincorporated dyes, elevated baseline, compression artifacts, mobility shifts, and footprints of earlier versions of the sequencing polymerases, that were misinterpreted by software or user. All of the above mentioned causes and artifacts can be identified and resolved by generating haplotypes with high quality sequence data that meet forensic guidelines, that is, the application of optimal chemistry and instrument conditions, fully redundant sequence coverage that is preferably, but not exclusively, produced with forward and reverse sequencing primers; multiple forward (or reverse) sequencing reactions, often from different primers, may also be used to confirm sequence data. Generally speaking, the quality of the raw sequence data dictates the type of coverage required to ensure unambiguous consensus haplotypes. Only artificial recombinants, the mix-up of separately amplified and sequenced hypervariable segments between samples cannot be detected or avoided by appropriate raw data. These can only be detected by consulting the phylogeny, as artificial recombinants result in implausible haplotypes. They can, however, be prevented by an adequate laboratory strategy that employs supervision at critical handling steps. As a consequence of the blind test results, new amplification and sequencing protocols were developed that target the entire CR and therefore not only increase the discrimination power of mtDNA testing compared to HVS-I and HVS-II analysis but also prevent artificial recombination and phantom mutations as a result of long, largely overlapping sequencing strands (Figure 1). Since the results of the blind tests indicated that manual transcription represents the most error-prone step in data handling, electronic transfer of data and a posteriori quality control of the data is critical. A robust method for detecting idiosyncrasies in mtDNA data is the application of quasi median networks (for explanation and an example, see elsewhere in this encyclopedia).

mtDNA Alignment – Phylogenetic Perspectives

As mentioned above, mtDNA variation is usually recorded relative to the rCRS. While this is straightforward for the vast majority of nucleotide positions, it has proven to be difficult for short sequence stretches that display length variation. Demonstrated by an even simpler scenario, the insertion of a nucleotide adjacent to an identical neighbor cannot be aligned in an unambiguous way, as 5' as well as 3' alignments are feasible. As an example, an additional T residue adjacent to the T at ntp 310, which is itself surrounded by C residues, could be called as 309.1T or 310.1T. There is no experimental solution to this problem as sequencing analysis does not capture the required information. This is why early guidelines recommended a 3' alignment rule to harmonize nomenclature. Still, mtDNA sequences were observed that allowed for more than one single alignment. Take as example 16189T (rCRS) that is surrounded by two small C-stretches (5 Cs up and 4 Cs downstream). Two transitions at ntps 16188 and 16189 could be called 16188T 16189C, which is however identical to the alignment 16188del

16193.1C. Since different representations of the same sequence motif may result in situations where a haplotype is missed in a database search, consistent representation of identical motifs is important in the forensic context.

In an attempt to achieve one unique alignment for all mtDNA haplotypes, rules were defined on the basis of a most parsimonious binary alignment to the rCRS, with hierarchical priorities to resolve ties. Although intended to facilitate and standardize mtDNA alignment, the rules have not routinely been applied in practice. However, as our general understanding of worldwide mtDNA diversity has increased, there are now many cases for which the evolution/origin of previously ambiguous sequence motifs (e.g., the 16188T 16189C vs. 16188del 16193C) can be determined. As a result, a phylogenetic approach to mtDNA alignment and nomenclature has been proposed (and is today still used by EMPOP, see elsewhere in this encyclopedia) where alignment is based on the phylogeny of mtDNA. Mutational events are inferred through comparison to the nearest known evolutionarily related sequences and therefore nomenclature is based on scientific grounds rather than a rule-based approach. In addition, by reflecting the evolutionary history of the mtDNA molecule, the phylogenetic approach allows for an estimation of the true genetic distance between the sequence and its nearest relatives. Most importantly, the phylogenetic approach extends on the convention of mtDNA annotation in related fields such as population genetics and medical genetics, between which data are shared with the forensic community on a regular basis.

A disadvantage with respect to database searches is the requirement that a forensic practitioner would need to be cognizant of the details of the phylogenetic annotation used in the database. Furthermore, it cannot be excluded that the nomenclature for a particular sequence motif may change over time, as additional phylogenetic knowledge is gained concerning the evolutionary history of the mutation events in question. Two major developments have taken place to overcome these limitations for forensic practice. First, a new search engine (SAM) has been developed and implemented in EMPOP that performs sequence queries independent of the haplotype alignment by converting all sequences into unaligned nucleotide strings that are then compared. This solution guarantees that database sequences are not missed due to different alignment, which is very important for retrieving objective database search results. Second, an internet-based library of established mtDNA haplogroups with corresponding signature mutations (Phylotree) was developed. It is based on established methods of phylogenetic inference and is updated on a regular basis as new mtDNA data become available. Phylotree is useful for identifying the haplogroup status of the haplotype in question, and this in turn permits both quality checks of the mtDNA data and inferences of phylogenetic or geographic information.

Practical Aspects of Forensic mtDNA Testing

mtDNA has found a vital niche in forensic DNA testing. Its abundance in the cell is much higher (up to several thousand copies) than nDNA (four template copies for polymerase chain reaction (PCR)), which correspondingly increases the chances that some copies of it survive in highly degraded forensic

samples. Therefore mtDNA testing permits the successful analysis of samples that would otherwise give no molecular result with commonly employed nuclear STR tests. Further, even distant maternally related individuals can provide a comparative reference sample to test for relatedness and thus human identification (mostly in conjunction with other evidence) is feasible across large pedigrees with mtDNA markers. These advantages led to the application of mtDNA in crime casework where degraded samples and samples with insufficient nDNA are to be tested. Also, mtDNA analysis was found useful for the identification of human remains where both inaccessible nDNA and lack of direct comparative samples is evident. Both applications are briefly discussed in the following.

mtDNA Analysis for Criminal Investigations

Hair is one of the most ubiquitous pieces of evidence found at the scene of crime. While living keratinocytes in the hair bulb contain nuclei and thus allow for successful STR analysis, the formation of keratinocytes in hair fibers is associated with a process that involves the breakdown of the nucleus and its DNA. There seem to be interindividual differences in DNA removal that are not yet fully understood, with some telogenic hair showing detectable traces of nDNA while the majority does not. As a result, nDNA typing is generally quite difficult with telogenic hair. Successful mtDNA typing, however, has been reported in a very high number of hair samples (>92%).

In analogy to population samples, it is also desirable to achieve full CR sequence coverage in hair (and other crime scene specimens), but full CR amplicons are unlikely to be successful in these cases. Therefore, novel multiplex strategies have been developed that amplify short overlapping segments (mini-amplicons) in a manner that the entire CR is fully captured by forward and reverse sequence strands (Figure 1).

It is relevant to know how much mtDNA is present in an extract from a forensic sample. Often, a maximum amount of the DNA extract is used for amplification of challenging samples or an mtDNA concentration is estimated on the basis of a nDNA quantification result, which can however often be misleading. It has proven useful to apply mtDNA-specific quantification assays – that are unfortunately not yet commercially available on a broad basis, but need to be set up by the individual laboratories – in order to determine the quantity and quality (extent of degradation) of the DNA. The resulting data provide important information to define an appropriate strategy for downstream analysis (Figure 1).

Point heteroplasmy

Point heteroplasmy seems more frequent in hair (12% in HVS-I/II) than in blood and buccal cells (6% for the entire CR). Systematic studies confirmed earlier single observations that mtDNA sequences between hairs of an individual can differ. The differences between hairs that were described in these cases covered a spectrum that ranged from hairs with varying heteroplasmic mixture ratios with opposed dominant variants to hairs with apparently homoplasmic states of both variants. It has been suggested that the mitochondrial load in hair mainly derives from keratinocytes and to a smaller extent from melanocytes, which, lacking mitosis, continue to produce mitochondria during the life cycle and therefore represent a

bottleneck through which heteroplasmic ratios can be shifted. This would also explain why heteroplasmic switches in hair shaft portions are observed on a regular basis rather than gradual changes along the length of the hair. Alternatively, *de novo* mutations may contribute to the pool of heteroplasmic observations. In fact, the majority of affected positions concur with those known as evolutionary hotspots; that is, affected positions (mutations) often coincide with fast mutating sites. In addition, the magnitude of mutational segregation within hair samples has been shown to be tractable. Heteroplasmy along any given hair shaft follows predictable patterns of increasing rarity with increasing heteroplasmic and homoplasmic differences.

From a practical standpoint, and as a result of these findings, it has been recommended that two independent portions of a single unknown hair should be analyzed, if available. This would not only address issues of heteroplasmy along the length of the hair, but would also serve to minimize artifacts due to contamination. In cases where similar haplotypes are found between evidence and reference samples, the analysis of multiple reference hairs may also be helpful. It is important to note that the interpretation of mtDNA evidence from hairs needs to follow different argumentation compared to other tissues (see the section 'Interpretation of mtDNA Evidence').

Length heteroplasmy

Length heteroplasmy describes the coexistence of multiple sequence lengths in the mtDNA of a sample. It is observed on a much more frequent basis than point heteroplasmy, at least given the detection limits of current sequencing approaches. The vast majority of length heteroplasmy occurs in the homopolymeric sequence segments such as the well-known C-stretches around ntps 16189, 310, and 573 in the mitochondrial CR. The mechanisms for the development of length heteroplasmy seem to be different at these three positions. The T residue at ntp 16189 in HVS-I separates two shorter C-tracts (5 and 4C residues in the rCRS, respectively) that merge to an uninterrupted stretch of 10 Cs when a transition at ntp 16189 is present. Depending on the phylogenetic background, this can occur at frequencies between 20 and 80% of the analyzed samples (e.g., 16189C is a basic signature mutation of hg B that can reach high frequencies in Eastern Asia and Native America). It has been determined that length heteroplasmy in C-stretches usually arises with more than eight consecutive C residues, as the polymerase seems to produce additional variants at that level and above. Therefore haplotypes showing 16189C and no other transition between 16183 and 16193 are almost always associated with pronounced length heteroplasmy with a strong tendency toward the formation of longer variants (up to 15C residues).

In contrast, length heteroplasmy in the C-stretch of HVS-II around position 310 is usually triggered by insertions of C residues between ntps 302 and 310, which increase the number of consecutive Cs to eight or more (the rCRS harbors seven Cs in this segment). Similar to HVS-I, longer heteroplasmic variants are then observed. The frequency of length heteroplasmy here has been found to be between 40 and 70%, although it should be noted that many studies do not report this phenomenon at all. Transitions at ntp 310 are relatively rare (and mostly hg-specific, e.g., hg U4a2). However, when

they do occur, they are accompanied by a reduction of the overall length of the heteroplasmic length variants, which is in contrast to the previously mentioned slippage events that extend the length of the C-stretch. The mechanisms of this difference at ntp 310 have not yet been fully explored. The formation of length heteroplasmy around position 573 (HVS-III) is rare and often hg-specific. The mechanism is similar to the one described for the C-stretch between ntps 302–310 and the formation of the length variants is driven by insertions of C residues between ntps 567 and 574.

Generally, differences in length heteroplasmy between otherwise identical mtDNA haplotypes are not regarded as criteria for exclusion, as it is known that hair and other tissues such as blood, buccal cells, or bone of an individual can display divergent patterns. In some laboratories, it is routine practice to not even record it. The collection of 'forensic data' in EMPOP reports the dominant type when multiple length heteroplasmic variants are present.

mtDNA Analysis in Human Identification

Large-scale human identification efforts involve the investigation of missing persons, victims of natural catastrophes (e.g., tsunami, earthquakes, and thunderstorms), victims from war episodes, as well as victims of terrorist attacks and accidents. The analysis of autosomal STRs is generally the prime choice in human ID cases, as the excellent power of discrimination of nDNA markers serves the purpose very well. However, the most challenging samples often require the analysis of mtDNA. Furthermore, mtDNA data are extremely useful when only maternally related individuals are available as reference to which the DNA results of unknown samples need to be compared. Also, the success rates in obtaining useful mtDNA haplotypes from those specimens that gave no or insufficient nDNA information are reported to be quite high (84%). The rate of point heteroplasmy was found to be similar to hair samples (10%).

Interpretation of mtDNA Evidence

A typical forensic scenario involves the analysis of questioned and reference samples, followed by a determination as to whether or not the mtDNA haplotypes recovered from those specimens are consistent. In this context, a determination of consistent suggests that the haplotypes (and thus questioned and reference sample) originate from the same maternal lineage. If so, the mtDNA haplotype in question is searched against mtDNA databases to determine its relative rarity and assess the statistical weight of the mtDNA evidence. As discussed before, tissues typically targeted with mtDNA markers, such as hair, may present slightly different mtDNA molecules compared to tissues that often serve as reference material, such as blood or buccal cells. It is therefore important to define interpretation rules that take this variation into account.

It has previously been defined that identical mtDNA sequences, as well as mtDNA sequences that differ only by heteroplasmic variation, cannot be excluded as deriving from a common maternal lineage regardless of the tissue involved.

It seems further settled that two or more differences between mtDNA sequences (barring differences in the

homopolymeric sequence stretches) exclude the samples as originating from a common maternal lineage. Careful analysis of the differing positions is important especially in tissues such as hair that show increased variation.

mtDNA sequences that differ only by a single mutation are more difficult to evaluate and therefore sometimes lead to inconclusive results. Taking the tissue variability into consideration, two mtDNA sequences may then still belong to the same matrilineage, especially if one of the involved samples is hair. The evaluation of the actual position is then of crucial importance: a difference at a rapidly evolving position may still comply with maternal relatedness of the two samples, whereas a difference at a stable position may be indicative of different maternal backgrounds. A very probative solution – if possible – is to extend the analysis range to other parts of the CR or the coding region. This has been successfully performed in many cases.

While the body of data has grown immensely in the past decade and will likely continue to do so with the introduction of faster sequencing technologies in the future, one may never be able to achieve an easy to define interpretation system for sequences that differ by single mutations, just as the variation in some tissues is unpredictable. However, new technical achievements may allow for a more comprehensive analysis range in the future that would restrict difficult constellations to a minimum.

Acknowledgments

Jodi Irwin (AFDIL, Rockville) and Harald Niederstätter (GMI, Innsbruck) are greatly acknowledged for their helpful comments on the manuscript. In addition, the author would like to thank Hans-Jürgen Bandelt (University of Hamburg), Arne Dür (University of Innsbruck), Sabine Lutz-Bonengel (University of Freiburg), Thomas Parsons (ICMP, Sarajevo), Lourdes Prieto (Police Madrid), and the scientific staff at the GMI Innsbruck for their continuous support and discussion on mtDNA matters.

STR Short tandem repeat

While human DNA testing for identification of a biological source of evidence is routine in forensic science laboratories, nonhuman DNA typing is still considered a specialty application. Nonhuman DNA can be a significant piece of associative evidence in a variety of forensic applications, ranging from animal cruelty cases to criminal cases that can help link people to crime scenes, or one person to another person. The types of nonhuman DNA that have been used in the past in forensic cases include animal DNA typing, microbial DNA typing of soil samples, and plant DNA typing. The scope of nonhuman DNA typing methods is expansive; therefore, as an introductory article, this article focuses on the common animal and microbial systems. Nonhuman DNA typing also encompasses wildlife applications, plants, pollen, and insects. Some of these techniques have been used for general research purposes and many have been applied to forensic casework as well. All these techniques are currently being researched further and could have a great impact on the field of forensic science in the future.

Animal DNA Typing

In the most recent National Pet Owners Survey, the American Pet Products Association reported that approximately 62% of households within the United States have a pet, with just fewer than 39 million houses owning a cat and just over 46 million houses owning a dog (<http://www.americanpetproducts.org>). Since cats and dogs are so prominent in the American household, their significance in forensic casework has become recognized over the years. In particular, samples of nonhuman blood, saliva, tissue, and hair can be used for both nuclear DNA typing and mitochondrial DNA typing of animals in a diverse range of cases with both criminal and civil applications. Just like humans, animals can be the victim, suspect, or witness, depending on the type of case. The animal can be the victim in cases of animal abuse, and DNA typing is sometimes a useful tool in these investigations to confirm a particular scene where, for example, an animal was beaten. There

are also cases in which an animal may need to be identified by DNA typing if the animal was stolen or the remains of the lost animal are found elsewhere. Evidence in animal abuse cases often includes tissue samples and blood samples. In cases of a missing pet, if the parents are available, samples can be collected to try to generate a known reference DNA profile by reconstructing genetic heritage, or if there are items known to have that pet's DNA (hair, saliva, etc.), these items can be used to try to generate a known DNA profile for that particular animal. This collection of known reference samples is similar to protocol for missing person casework. Canines, in particular, can also become the suspect in cases of animal attacks on humans or other animals, as well as cases where an animal gets loose and causes damage to property or individuals. In these types of cases, evidence needs to be collected that could potentially contain biological material from the suspect animal. This can include clothes from a human victim and swabs of the victim's skin, and if the victim is another animal, samples of fur with the potential of containing the attacker's saliva can be used, but it is important to try to sample areas where the victim's blood is not present. This is to avoid the victim DNA from becoming the predominant profile, and thus masking the minor DNA sample of the attacker. Also, the attacker should be examined for the presence of hairs or other materials from the victim in the mouth or the claws. Lastly, animals can play the role of a silent witness in which DNA from biological fluids or hair can help link a victim's pet to a suspect or crime scene or the suspect's pet to the victim or crime scene. Hair is the most common finding in these types of cases since the animal naturally sheds hair into the environment and hairs tend to cling to things in the surrounding areas. There are a number of laboratories that conduct animal DNA testing including QuestGen Forensics (Davis, CA) and the Veterinary Genetics Laboratory at UC Davis (Davis, CA). Although many criminal investigations may use human DNA typing to aid in an investigation, clearly animal DNA typing can be very useful in a variety of civil cases as well.

Canine DNA Typing

Canine DNA typing has been used and deemed admissible in court in a variety of types of cases including the dog as a silent witness, the dog as the suspect in the case, and the dog as the victim in cases of animal abuse. Numerous cases are summarized on the Denver DA web site (<http://www.denverda.org>) and the QuestGen Forensics closed casework list on their web site (<http://www.questgen.biz>). One of the earliest cases noted on the QuestGen Forensics web site was a case that occurred in Canada in which a man and his dog were murdered and a mixed bloodstain from each victim was found on the suspects' jeans, with the nonhuman portion matching the dog. There are also cases listed using both STR and mitochondrial DNA typing techniques on hairs and bodily fluids showing the wide range of applications evidence from canines can have in forensic investigations.

Short tandem repeat typing of canine DNA samples

Canine STR markers have been researched over the years for forensic science applications and a kit has been developed to enable forensic DNA analysts to type this species for casework. The California Department of Justice, the National Institute of Standards and Technology, the National Institute of Health, the Federal Bureau of Investigation, MMI Genomics, and Finnzymes collaborated with research scientists to create a kit for canine STR typing for forensic applications. The Finnzymes Canine 2.1 Multiplex STR Reagent Kit uses fluorescent detection technology to enable robust and reliable STR typing of canine DNA samples. The 18 STRs chosen are unlinked (physically map to different chromosomes) and the criteria for these chosen loci were similar to the human loci used in human STR testing. The kit also has a gender identification element and the zinc finger gene in canines. Dogs commonly involved in forensic cases, along with both mixed and pure breed dogs, were profiled with this kit and validated for forensic applications. The loci used in the kit were determined to have high variation, proved to be individualizing for dogs, and provided a standardized STR panel for forensic DNA analysts to use in casework involving samples from canines. There are other commercial STR kits available for canine typing; the StockMarks kit for canines is from Applied Biosystems Inc. (Foster City, CA) and contains supplies to PCR amplify 10 STR markers approved by the American Kennel Club (AKC). The methods for canine DNA extraction, quantitation, amplification, separation, and detection are all easy to adapt in forensic science laboratories because these methods are already being used for human DNA analysis and other nonhuman DNA typing applications. The UC Davis Veterinary Genetics Laboratory (Davis, CA), as well as other agencies, also uses a Canine CODIS, similar to the human version, in order to help stop dog fighting crimes and form linkages between dogs and breeders. Overall, canine STRs are individualizing and useful for cases involving dog attacks and animal abuse or in situations where canine samples can help link people to crimes or crime scenes. One case on the Denver DA web site (<http://www.denverda.org>) that illustrates this involved DNA testing of feces found on the bottom of shoes believed to have been worn by the suspect on the day the crime had occurred. The DNA profile generated was compared to the profile of the dog that produced the feces

at the crime scene, and it was determined that the feces on the shoe was consistent with coming from the same animal.

Mitochondrial DNA typing of canine DNA samples

Just as with human DNA typing applications, when dog hair becomes a piece of evidence, there is not always sufficient root tissue material available for STR analysis. As a result, a less discriminating but more successful test known as mitochondrial DNA typing can be performed on these samples. Even though this test is not as good for individualization as nuclear DNA tests, it can be an important tool to make exclusions in a case by testing sequence variation within the control region, especially the hypervariable regions, of the mitochondria. One particular study experimented with a short fragment within the hypervariable region 1 that has a low mutation rate and contains single nucleotide polymorphisms and concluded that this was a good method when working with potentially degraded samples. This is important because mitochondrial DNA typing can be the method of choice when samples are degraded in order to have a better chance at obtaining a profile just as when working with highly degraded DNA or skeletal remains in human identification. Mitochondrial DNA typing of this region was also determined to be species specific and a rapid way to screen multiple samples for exclusion of potential suspect canines in a case. It is important that this test is specific to canines because cat hairs can also often be found at crime scenes and humans are handling these samples, so this method should not be sensitive to human, feline, and canine-related species (wolves). Overall, these regions have sufficient variability and high exclusionary rates and therefore are good methods for mitochondrial DNA typing of canine hair samples. One case noted on the Denver DA web site (<http://www.denverda.org>) involves a homicide in which mitochondrial DNA testing of dog hairs found on the rope and tape used to bind the murder victim yielded results that were consistent with the mitochondrial sequence of the suspect's dog. This evidence was not individualizing but was used in this case against the suspect and aided the overall investigation.

Feline DNA Typing

Feline DNA typing has been used in forensic casework, with the main focus on cases of a domestic cat playing the role of a silent witness by linking people to people, or people to scenes, or in cases of animal abuse. The first forensic case and probably one of the most famous to date involving feline DNA typing was the case of a cat named Snowball in Canada. A woman had gone missing from her home and her bloodstained car was found nearby. A bag was also found, containing bloodstained shoes and a coat lined with white hairs in the interior, nearby to the victim's home. The blood on the shoes matched that of the victim, and the hairs were determined to be consistent with cat hairs. These hairs were later typed for DNA and compared to a known reference sample from the primary suspect's cat and determined to be a match, and thus the suspect was convicted of the crime. One of the companies that performs STR and mitochondrial DNA typing on animal samples, QuestGen Forensics, notes a case in a list of closed casework from Iowa in 2003 on their web site (<http://www.questgen.biz>) from Iowa in 2003, in which, a woman went missing and her body was

found bound in fabric containing cat hairs. Mitochondrial DNA testing was performed on the cat hairs and it was determined that the cats at the household where the fabric was believed to have come from had mitochondrial haplotypes that could not be excluded; therefore, they could be the source of the hairs on the fabric. This evidence along with other evidence resulted in the primary suspect being convicted of the crime. Other criminal and animal abuse cases have been noted involving feline DNA typing, and brief synopses of some of these cases can be found on the Denver DA web site (<http://www.denverda.org>). These cases show that feline DNA typing has proven to be significant in forensic investigations in the past, this type of evidence and testing has been admissible in court, and therefore, DNA typing of feline DNA is expected to play a significant role in a variety of future forensic casework applications.

Short tandem repeat typing of feline DNA samples

Feline STR markers have been researched over the years, and a commercial kit has been developed to enable forensic DNA analysts to type this species for forensic applications. The National Cancer Institute's (NCI) Laboratory of Genomic Diversity and the National Institute of Standards and Technology (NIST) and Promega Corporation (Madison, WI) joined forces to develop the MeowPlex STR typing kit, with the intention of creating a multiplex assay using polymorphic tetranucleotide STR loci with characteristics consistent with those of the 13-core CODIS loci used in STR typing of human DNA. There are certain requirements to pick the candidate STR loci for a DNA typing kit for humans, and these criteria were used to choose feline STR loci as well. The loci chosen not only had to be tetranucleotide markers but also needed to be robust and reproducible, to be genetically unlinked, and to have low mutation rates and high discriminating power. Loci that meet these criteria and that follow Mendelian genetic patterns are able to be used in statistical calculations of significance with population databases generated for feline species. The STR markers that were chosen for this kit resulted from experiments with 22 candidate loci tested among 200 cat DNA samples representing just fewer than 30 breeds. The 11 markers chosen were determined to be highly polymorphic and robust enough for a multiplex assay necessary to obtain desirable results in future applications. Along with these markers, a gender marker for the Y chromosome in domestic cats was added in order to simultaneously determine the sex of the cat. This multiplex kit works similarly to human DNA typing kits in which a dye-labeling and capillary electrophoresis system is used to separate loci of overlapping sizes and small amounts of sample are required for typing. The PCR conditions for this assay are similar to those for human DNA typing; therefore, this is a method that can be done in a forensic laboratory where human DNA typing is already being performed for forensic casework. Quantitative PCR assays have also been researched and developed in studies in the past. Another important development came about when a population database was generated for feline STR testing as a reference for statistical analysis. The domestic cat breeds recognized by the largest registries in the United States were all sampled (buccal swab or blood sample) and typed with the polymorphic loci from the feline multiplex

kit in order to generate a reference population database for feline STR typing. Fewer than 40 breeds were represented with a sample size of over 1000, and the heterozygosity values ranged from average to high for these loci within the various breeds. With the creation of this database, forensic DNA samples from felines could now be typed with a robust multiplex kit and the data could be given significance by the use of population statistics in court. Lastly, this kit was also determined to be specific to feline species and some other closely related relatives along with a few other mammals, but was not sensitive to human DNA. Another significant development in feline STR typing research has been the use of a real-time PCR assay that quantitates the amount of starting DNA template sample prior to amplification of the sample. This works a lot like the methods performed for human samples but is not species specific for felines, which is not a huge legal issue due to the lack of mixtures anticipated in these types of cases. This assay proved to be very rapid and extremely sensitive with very low quantities of DNA (23 pg). Therefore, feline short tandem repeat (STR) DNA can be extracted, quantitated, amplified with a multiplex assay, and separated and detected successfully and has proven to be significantly valuable biological evidence in a number of forensic science cases.

Mitochondrial DNA typing of feline DNA samples

Mitochondrial DNA typing of felines can be used on hair samples if sufficient root material is unavailable for STR testing of feline DNA. Since it is very common for cats to shed their hairs and leave them behind on nearby surfaces in the environment they live in, many of these hairs will not contain tissue material for STR typing, and therefore mitochondrial DNA typing is the only option. The entire mitochondrial DNA genome of the domestic cat has been sequenced. In a recent study, randomly bred cats from four different regions across the United States were tested for variation across feline mitotypes to show that mitochondrial DNA typing could be useful for forensic investigations. This study discusses how although STR typing is usually preferred over mitochondrial DNA typing, the latter has been used successfully in several previous forensic investigations involving homicide. It was determined that of the 174 cat hair samples tested, 32 mitotypes were able to be differentiated, with four of the most common types seen across all four regions of the United States. The results obtained were consistent with having enough variation for forensic testing of these mitochondrial DNA sequences within the feline population and that certain results showed that substructure should not be a big issue for court acceptance. This study also suggests that there may be other variations of mitotypes across cat populations in the United States, which would give an even higher power of discrimination to mitochondrial DNA typing of felines and are being further researched. Another study also researched nonrepetitive areas of the control region in feline mitochondrial DNA for its use in forensic evidence databases. A good amount of research has been conducted on feline mitochondrial DNA, and this area of nonhuman DNA typing will be further studied in the future and be utilized more often in forensic investigations.

Implications for the Future of Animal DNA Typing in Forensic Casework

The use of canine and feline DNA typing in forensic science will continue to grow in the future and is a significant tool for assisting in investigations. Multiplex kits may be further developed by the addition of extra loci and then commercialized for use. Training programs are critical for more laboratories to begin to perform these assays on these types of samples on a routine basis. Currently, only a few specialized public laboratories and a handful of private laboratories offer this testing to law enforcement, prosecutors, or defense attorneys. The use of DNA typing of canine and feline samples in forensic casework will continue to grow in the future.

Plant DNA Typing

DNA typing of trace evidence from plant materials can be used in forensic investigations to help link suspects to crime scenes or to other people involved in a case. The Palo Verde case that occurred in Arizona in 1992 is a well-known example of when DNA typing from seeds was used to help link the suspect to the crime scene in a homicide case (<http://www.denverda.org>). In this case, the body of the victim was located by an area containing Palo Verde trees in which one tree at the scene contained abrasions on the bark consistent with an object backing into its surface. Two seeds were found in the bed of the suspect's pickup truck, which were later determined to be consistent with coming from that particular Palo Verde tree at the scene using randomly amplified polymorphic DNA (RAPD) technology. The plant material served as associative evidence that helped to convict the suspect in this particular case, along with other physical evidence. DNA typing of plant material has been researched extensively in recent years for its application in forensic casework. There are a number of different types of plant material that have been tested, including opium poppy, a variety of grasses and trees, as well as other plant species. Also, *Cannabis sativa* STRs have been studied extensively for forensic application, and databases for these types of samples have been studied for use in investigations. *C. sativa* has been studied not only in drug investigations but also as a fiber type in the form of hemp. DNA typing of these types of biological samples can help form linkages in a forensic investigation, just as previously described for animal samples.

There are a variety of technologies used for plant DNA typing and have been applied in cases. Different types of plant materials can be extracted and purified using a combination of liquid nitrogen and a variety of available kits, complete with reagents and required materials, in order to recover DNA and attempt to remove PCR inhibitors. Some of the kits commercially available are Qiagen kits (Valencia, CA) including the DNeasy Plant Miniprep Kit, Qiagen DNeasy Plant Mini Kit, DNeasy Plant Maxi Kit, and the DNeasy 96 Plant kit for high-throughput processing of plant samples. Other kits include the MasterPure™ Plant Leaf DNA Purification Kit and the QuickExtract™ Plant DNA Extraction Solution both by Epicentre Biotechnologies (Madison, WI) and the UltraClean Plant DNA Isolation Kit (MO BIO Laboratories, Inc., Carlsbad, CA). Microsatellites such as STRs and short sequence repeats (SSRs)

from plant material including DNA from seeds, leaves, and other trace materials can be used to compare crime scene evidence to known samples of different species of trees. These markers follow Mendelian genetics and have the other desired qualities of markers chosen for DNA typing methodologies due to variability, short length, prevalence, and reproducibility. Amplified fragment length polymorphism (AFLP) is a rapid method that can be used in cases where a particular plant species has not been sequenced in the past and no known STRs have been identified. After extraction and purification, samples can be PCR-amplified similar to methods used for human and other nonhuman DNA in order to obtain the necessary quantity of DNA for separation and detection by capillary electrophoresis, gel electrophoresis methods, or sequencing technologies.

Insect DNA Typing

Forensic entomologists study insects found on decomposing bodies to help determine the time of death and other aspects of an investigation. The insects commonly found on decomposing bodies can vary by species, but the morphologies can be similar between them, and therefore, DNA typing can be helpful to distinguish between insect species. A number of insect species found on bodies in death investigations have been studied for the potential to individualize through DNA analysis. Also, different methods of DNA analysis have been studied and utilized in these types of forensic investigations, mostly involving regions of mitochondrial DNA. A number of DNA extraction methods are also available that can be used to obtain insect DNA for further analysis. FTA cards have been successfully used for the extraction and storage of insect DNA samples. There are also DNA extraction kits available from a variety of companies. Among these are the Genomic DNA Extraction Kit for Arthropod Samples by Cartagen Molecular, Inc. (San Carlos, CA) and the E.Z.N.A Insect DNA Kit (Omega Bio-Tek, Norcross, GA).

Diptera larvae have forensic entomological significance and are often difficult to distinguish by morphology and therefore have been studied to see if DNA analysis is a more precise method for identification between species. PCR-RFLP has been used to differentiate between most Diptera families, such as calliphoridae, muscidae, and sarcophagidae, by amplifying and detecting sequences within the internal transcribed spacer (ITS) regions of the ribosomal DNA gene repeat. Both sequence and length variation within the mitochondrial DNA control region of Diptera calliphoridae species and the subunits of the cytochrome oxidase (COI or COII) gene in Diptera calliphoridae, sarcophagidae, and phoridae have been researched for forensic entomological applications. Regions of ribosomal RNA have been studied and used to differentiate between different insect species, including the 16S rRNA region within Diptera muscidae, the 28S rRNA gene within Diptera calliphoridae, and the 18S–28S rRNA genes within the various Diptera species. Often empty puparial cases and other fragments left behind by the flies are found on decomposing bodies and could potentially be used for DNA analysis to identify the fly species if degradation is not an issue. Although studies have

been conducted on insect species commonly found on human remains and certain species have been identified through DNA analysis, more research and validation studies need to be conducted for insect DNA analysis to be more widely utilized in the forensic community.

Microbial DNA Typing from Soil Samples

Just as in situations involving animals, insects, or plants, microbes can be DNA-typed in a variety of soil samples for use in forensic investigations. Soil is sometimes an important piece of evidence in a case, and it can be used to help link people or evidence to specific scenes using a variety of different methods. Other than looking at the physical characteristic differences between soils in different locales, there are also microbes within the soil that can be characterized for forensic analyses. The similarities between samples coming from the same location, differences in bacterial composition existing between various locations, and changes in bacterial communities within soil samples have all been studied to see if bacterial DNA typing of soil samples can be effective in forensic investigations.

Extraction of Microbial DNA in Soil Samples

In order to be able to further distinguish these samples, the DNA needs to first be extracted from the soil, which requires breaking open cells to recover DNA. As with human DNA typing methods, polymerase chain reaction (PCR) inhibitors can sometimes be recovered along with the DNA with the use of certain extraction methods. This is one of the problems that analysts encounter with soil DNA typing because soil samples frequently contain chemical contaminants. A study on the potential of bacterial DNA typing for forensic use discussed that humic acids are a typical component within some soil samples and that this chemical is a known PCR inhibitor.

Although there is not a universal standard for the method of DNA extraction for soil samples due to differences in soil origins, commercial kits are now available for forensic purposes. As with human applications, samples may sometimes need to be diluted, further purified, or chemically modified to diminish the presence of PCR inhibitors in an attempt to prevent problems during DNA typing. These kits contain the proper elements to assist the analyst with these potential problems and allow the analyst to obtain DNA that is ready for PCR. A kit that is available for forensic use is the UltraClean Soil DNA Isolation Kit (MO BIO Laboratories, Inc., Carlsbad, CA), which contains reagents for extraction and purification aimed at lessening the presence of PCR inhibitors in soil samples (<http://www.mobio.com>). The use of a bead solution, along with heat, detergent, and vortex action, allows this kit to concentrate DNA onto a silica filter, which can then be recovered by a wash step for further processing. The same company also makes a PowerSoil DNA Isolation Kit that can be used with more difficult and complex soil samples. The SoilMaster DNA Extraction Kit (Epicentre Biotechnologies, Madison, WI) utilizes spin column technology, cell lysis

conditions, and chromatography in order to recover DNA that can then be amplified by the polymerase chain reaction (<http://www.epibio.com>). Each of the kits provide detailed protocols, alternative troubleshooting options, and reagents favoring the removal of chemical inhibitors, as well as a goal of maximizing DNA quality. These kits are easy to use and do not require an overabundance of time. Other kits made by different companies are also available to forensic analysts for soil DNA extraction, including the Soil DNA Isolation Kit (Norgen Biotech Corp., Ontario, Canada) and the E.Z.N.A. Soil DNA Kit (Omega Bio-Tek, Norcross, GA).

Amplification and Typing of Microbial DNA in Soil Samples

Since forensic science laboratories routinely use PCR amplification and automated DNA sequencing instrumentation to amplify and process samples, a variety of DNA analysis methods can be used. AFLP uses restriction enzymes to digest sequences of DNA-containing adaptors that are recognized by primers resulting in amplified product that can be detected on a polyacrylamide gel or by capillary electrophoresis. Automated-ribosomal intergenic spacer analysis (A-RISA) can also be used to amplify sequences of interest located between genes for the small and large ribosomal subunits, and the amplification product can be detected on a silver-stained gel. Amplicon length heterogeneity-PCR (LH-PCR) has been studied as a way of detecting changes in bacterial composition of soils associated with decomposing cadavers. Terminal restriction fragment length polymorphism (T-RFLP) is another method that has been studied for DNA typing of soil samples. The terminal fragments of 16S ribosomal gene, as well as other genes, have been amplified, digested, and fluorescently tagged for detection during electrophoresis. This method has detected differences between soil samples from nearby differing locations (sampling comparisons), but further studies need to be done on the differences in microbial communities within stratified regions of the same soil (depth comparisons). The resulting T-RFLP data is less difficult to interpret and the sensitivity is sufficient for forensic applications.

Implications for the Future of Microbial DNA Typing of Soil Samples in Forensic Casework

In order to perform any of these methods, certain equipment and instrumentation are needed that are all readily available in a forensic DNA laboratory, and therefore, soil DNA typing can be easily adapted within laboratories with proper training. Since sufficient variation can exist in soil samples, DNA typing of these types of samples is a potentially useful application in forensic DNA laboratories. Although bacterial DNA typing of soil samples can be a useful application in the field of forensic science, processing this evidence can be very challenging for forensic scientists. The challenges associated with this method include variability of bacteria within soil samples due to environmental differences and changes and soil stratification and the necessary conditions required to process these types of evidentiary samples, and additional validation studies are essential for the overall success of this method.

Glossary

Next-generation sequencing technologies High-throughput sequencing technologies that parallelize the sequencing process, producing millions of sequences at once

at a much lower per-base cost than conventional Sanger sequencing.

Targeted enrichment Methods to enrich a sequence library for specific regions of a genome.

Introduction

In the last few years, massively parallel DNA-sequencing platforms, known as next-generation sequencing (NGS) technologies, have been developed to make feasible to directly sequence the whole genome of an individual in a few days. Thus, it would provide a powerful tool to study DNA and RNA samples.

These technological advances open up new opportunities for many applications such as whole genome and targeted resequencing, sequencing *de novo*, expression analysis, and epigenetic studies.

In some cases, instead of using the general term of NGS, these technologies are referred to as second- and third-generation sequencing. Second generation sequencing technologies are the ones that require a clonal amplification step previously to the sequence reaction, whereas third generation sequencing are based on single-molecule sequencing, being Sanger sequencing the first generation.

There are currently several commercially available NGS platforms and still a few more in development. The goal of these technologies is to sequence a whole human genome for \$1000 and it seems that this purpose could be reached by the end of 2012. According to the press release of two different companies, Life Technologies, with the new platform Ion Proton and Illumina with HiSeq 2500, both will be able to sequence the whole human genome in several hours.

In addition to the technological characteristics of the platforms, it is very important to consider the amount of data produced by these platforms, making bioinformatics support extremely crucial.

In the forensic field, some disciplines could immediately benefit from its application, while others would require additional studies before deciding whether they could be incorporated.

Next-Generation Sequencing Technologies

NGS workflow can be divided into template preparation, sequencing, and data analysis.

Template preparation for genomic applications on NGS platforms involves several steps such as follows: random shearing of DNA into smaller sizes, library preparation, capture of the regions of interest in the case of targeted resequencing application, and clonal amplification, with the exception of those technologies based on single-molecule sequencing.

During the process of capturing and library preparation, it is possible to barcode samples, which enables one to pool multiple samples per sequencing run, taking the advantage of the high throughput of the NGS platforms.

The amount of DNA required is determined by the type of library, the capture method, and the sequencing technology altogether. As each method has advantages and drawbacks, all these factors need to be considered in order to select the best approach for each application.

As mentioned earlier, the difference between what is called second- and third-generation platforms is the existence of an amplification step prior to sequencing reaction. The technologies that required a previous amplification step perform clonally amplification of the templates either on the surface of beads in emulsion polymerase chain reaction (PCR) or on a glass support. The first one is used by 454 Roche, SOLiD, and Ion Torrent. Illumina relies on a bridge PCR on a glass slide to amplify small fragments of DNA. In this approach, forward and reverse PCR primers are attached to a solid surface, and, as a consequence of this, amplification products originated from any single template molecule remain immobilized and clustered to a physical position on the slide.

Nowadays, there are different sequencing strategies that can be generally grouped in sequencing by synthesis that comprises nucleotide incorporation by a polymerase or in sequencing by ligation which is based on the use of DNA ligases (Table 1). In addition to this, new methods are being developed as the ones based on nanopores; even so, they are not yet commercially available.

Although NGS platforms such as 454 Roche, Illumina, Ion Torrent, Helicos, and Pacific BS rely on sequencing by synthesis, there are important differences among them.

The 454 Roche was the first NGS platform available as a commercial product. Sequencing is performed by pyrosequencing. In this method, the incorporation of a nucleotide by DNA polymerase results in the release of pyrophosphate, which initiates a series of downstream reactions that ultimately produce light by a luciferase. The light can be correlated with specific nucleotide incorporation because they are added following a sequential order. This is one of the sequencing technologies with longer reads, up to 1000 bp.

The Illumina system is based on sequencing by synthesis in which all four nucleotides are added simultaneously to the flow cell channels, along with the polymerase, for incorporation into the oligo-primed cluster fragments obtained after bridge PCR.

Table 1 Comparison of next-generation sequencing (NGS) platforms commercially available

Technology	Amplification method	Sequencing method	Instrument	Read length (bp)	Throughput (Mb/run)	Run time	Website
454	Emulsion PCR	Synthesis (pyrosequencing)	454-GS Junior	400	50 Mb	10 h	http://www.illumina.com
Illumina	Bridge PCR	Synthesis	454-FLX+	700	900 Mb	23 h	http://www.illumina.com
			Illumina-MiSeq	150 + 150	>1 Gb	27 h	
			Illumina-GAI	150 + 150	95 Gb	14 days	
			Illumina-HiScanSQ	100 + 100	150 Gb	11 days	
			Illumina-HiSeq1000	100 + 100	300 Gb	11 days	
			Illumina-HiSeq2000	100 + 100	600 Gb	11 days	
SOLiD	Emulsion PCR	Ligation	SOLiD-5500	75 + 35	90 Gb	7 days	http://www.lifetechnologies.com
			SOLiD-5500xl	75 + 35	180 Gb	7 days	
			Ion Torrent	Emulsion PCR	Synthesis (H ⁺ detection)	Ion PGM – 314 chip	
Ion PGM – 316 chip	200	>100 Mb				2 h	
Ion PGM – 318 chip	200	>1 Gb				2 h	

Unlike 454, fluorescently labeled nucleotide terminators are used on this platform. The maximum read length is 150 bp.

In the case of the Ion PGM Sequencer (Life Technologies), sequence data are obtained by directly sensing the ions produced by template-directed DNA polymerase synthesis using all natural nucleotides on the ion chip. The ion chip contains ion-sensitive, field-effect transistor-based sensors in millions of wells, which allow parallel and simultaneous detection of independent sequencing reactions. Unlike the other technologies in which the throughput is determined by the equipment, the Ion PGM throughput is determined by the chip used for sequencing. There are currently three chips available with a capacity of 10 Mb to 1 Gb. The read length achieved with this platform is 200 bp. Life Technologies has announced the release of a new platform in 2012 called Ion Proton Sequencer based on the same technology as Ion PGM, but with a higher capacity. With the Ion Proton Chip I, it would be possible to sequence two exomes, whereas, with the Ion Proton Chip II, the whole human genome would be sequenced for \$1000 in several hours.

NGS platforms that are based on single-molecule sequencing such as Helicos Biosciences and Pacific Biosciences, in which sequencing is performed directly on the DNA, seem to be very promising as they would avoid any amplification step.

The Helicos system was the first commercial release of a single-molecule sequencing instrument. The DNA fragments are hybridized to primers covalently anchored in random positions on a glass cover slip in a flow cell. The primer, polymerase, and labeled nucleotides are added to the glass support. The base incorporated into the synthesis strand is determined by analysis of the emitted fluorescence signal. Like in other platforms, many millions of fragments are sequenced at the same time.

The PacBio BS is a single-molecule and real-time sequencing system. The main difference compared with any other technology is that single polymerase molecules are attached to the solid support and it provides an extra-long read.

The SOLiD system is based on sequencing by ligation and the use of two-base encoded probes. A universal sequencing primer is hybridized to templates and a pool of fluorescently

labeled octamer probes, containing all possible combinations of A, C, G, and T at positions 1–5, interrogates the sequence of the unknown template on each bead. Only the probe homologous to the first five bases of the template will be ligated to the universal sequencing primer. Up to 15 cycles of ligation, detection and cleavage record the color at every fifth position, given a maximum length read of 75 bp.

Targeted Enrichment

Methods for capturing regions of interest when a particular portion of the genome need to be analyzed have been developed, allowing to reduce costs and efforts significantly compared with whole-genome sequencing.

Considering even the different capture strategies, the workflow for targeted resequencing for candidate regions, genes, or exome sequencing is very similar. Depending on the method used for capturing the regions of interest, the capture occurs before or after creating the library. Once the capture library is created, it is clonally amplified followed by massive parallel sequencing.

Capture strategies can be broadly grouped into three main groups (Table 2).

PCR Amplification

A PCR is used to amplify the region of interest. The main advantage of this technique is the small amount of starting material required. Considering that the amount of DNA is a major limitation in forensic samples, the strategies based on the PCR approach seem to be the most suitable for forensic analyses.

If the region of interest is a large kilobase-sized, contiguous region, long PCR using high-fidelity polymerases could be used.

On the other hand, different strategies have been developed over the last few years to amplify simultaneously hundreds of fragments of DNA when required. Access Array System (Fluidigm) uses a microfluidic chip with nanoliter-scale chambers, where the simultaneous amplification of 48 different

fragments in 48 samples is performed. By incorporating the adaptor sequences into the primer design, the amplicon products are ready to go directly into clonal amplification.

Microdroplet-PCR technology developed by RainDance involves the use of emulsion PCR in a microfluidic device, creating droplets of primers in oil solution. The primer droplets that are targeted to different regions of the genome merge with separate droplets that contain fragmented genomic DNA and PCR reagents. These mixed droplets are thermal cycled in a single tube. The encapsulation of microdroplet PCR reactions prevents possible primer-pair interactions, allowing an efficient simultaneous amplification of up to 20 000 targeted sequences.

Illumina and Life Technologies have followed similar strategies to capture regions for MiSeq and Ion PGM Sequencer, respectively. Illumina has launched the TrueSeq Custom Amplicon Kit for multiplex amplification of up to 384 amplicons per sample. Life Technologies has recently developed a multiplex PCR to amplify, in a single tube, up to 480 amplicons known as Ion AmpliSeq Cancer Panel. Only the cancer panel is currently available; however, it has been announced by the company that custom panels for up to 1536 amplicons would be soon available.

Circularization

Enrichment by DNA fragment circularization is based on the use of probes comprising a single-stranded DNA oligonucleotide that contains two sequences at its ends that are complementary to noncontiguous stretches of a target genomic fragment, but in a reversed linear order. Specific hybridization among probes and complementary genomic DNA generates circular DNA, which is amplified through rolling circle amplification.

Halo Genomics has developed two different strategies based on the circularization method, Selector and HaloPlex. The first one, Selector Target Enrichment system, is based on multiple displacement amplification. This strategy produces circular DNA that is amplified in a whole-genome amplification reaction. The resulting high-molecular DNA product is compatible with all NGS library preparation protocols. To achieve this, DNA sample is first fragmented using restriction enzymes. After that, the probe library is added so as to hybridize the targeted fragments. Each probe is an oligonucleotide designed to hybridize both ends of a targeted DNA restriction fragment, thereby guiding the targeted fragments to form circular DNA molecules. The circular molecules are closed by ligation and then amplified. The next step is library preparation.

In the case of HaloPlex technology, PCR products are ready for pooling and direct sequencing. It is not necessary to create the library after the capturing since the probes also contain a specific sequencing motif that is incorporated during the circularization. This motif allows the incorporation of specific library adaptors and barcodes during the amplification. At present, this product is optimized only for Illumina.

Hybridization

Enrichment by hybridization is based on the hybridization of specific probes complementary of the regions of interest with the input sample, either in solution or on a solid support. The first hybridization approaches were based on array capture, but it is currently more extended the use of in-solution hybridization. Fragment libraries are hybridized to biotinylated probes in solution and subsequently recovered with streptavidin-magnetic beads, amplified and sequenced in the platform of choice.

All vendors (Agilent, Nimblegen, Illumina, and Life Technologies) offer either kits predesigned for specific applications such as exome sequencing, cancer, etc. or custom panels to be designed by the user. There are diverse kits for different sizes of the region of interest from a range less than 100 kb up to 60 Mb.

Applications in Forensic Sciences

Nowadays, it is not certain whether the use of NGS technologies would be extended in forensics in the near future or whether they will replace current technologies, as very few forensic laboratories have started to test them. Needless to say, that in some forensic disciplines, NGS would provide additional and powerful tools to solve problems not yet resolved. It is important to remind that before its use in real casework, it would be necessary to assess the sensitivity, specificity, and accuracy of each approach.

In forensic genetics, short tandem repeats (STRs) are routinely used for human identification. Current methods are PCR-based fragment analysis and capillary electrophoresis, estimating the number of repeat units of each marker. The use of NGS allows detecting not only the number of repeats, but also single base pair substitutions or repeating structure variation. As the STRs used in forensic casework are usually between 100 and 500 bp, only the NGS technologies with long reads are compatible with this application.

NGS could provide a rapid, high-throughput and cost-effective tool for mitochondrial DNA sequencing, while its use in forensics would require to optimize the protocols altogether with the algorithm analysis in order to get quality data to meet forensic criteria.

It is very common that forensic samples are easily degraded; so, in these cases, NGS technologies with short reads would be more appropriate.

Sudden cardiac death is a challenging problem in forensic pathology because the cause of the death is in many cases not detectable during autopsy. Several genetic cardiac disorders such as arrhythmogenic abnormalities and structural cardiomyopathies are associated with sudden death. The analysis of genes involved in these pathologies would help in the diagnosis, not only improving the search for the cause of death but also allowing genetic counseling of relatives at risk. Genetic diagnosis of these diseases is not easy as they are genetically heterogeneous. However, using NGS it is possible to perform a targeted resequencing of all the genes associated with genetic cardiac disorders or even the whole exome.

In the field of microbial forensics, whole-genome sequencing is a powerful tool for microbial genome characterization. The identification of the pathogen and its origin is crucial in criminal investigation of bioterrorism attacks and epidemiological investigation. Its usefulness in this field has been demonstrated by the sequencing of the German enterohemorrhagic *Escherichia coli* O104:H4 outbreak in May 2011. Previously, other microbial pathogens such as *Bacillus anthracis* and *Yersinia pestis* have been already characterized using NGS. Previous methods were limited to Sanger sequencing of a small number of strains or isolates to identify potentially informative markers, followed by genotyping of selected markers in additional strands, whereas NGS makes feasible the sequencing in parallel of multiple bacterial genomes in a short period of time and at a relatively low cost.

DNA – Statistical Probability

Introduction

Human individualization based on the genome exploits the fact that everyone except for identical twins is genetically distinguishable. Moreover, human genetic material is found in every nucleated cell in the body and can be recovered from samples as diverse as bone, blood stains, ear wax, or shaver clippings. DNA may be recovered from very old samples that have been well preserved, and DNA signatures may be preserved even over successive generations.

The very genetic nature of DNA evidence that makes it of such value to forensic science also brings particular problems in interpretation. One problem is that as more and more genetic loci are used for DNA profiles, the proportion of a population who might be expected to share a particular profile becomes less. There comes a point where any attempt to quantify the probability of seeing a profile strains credulity. Certainly numbers such as one in several trillion fall into that range. Another problem is that the genetic constitution of a population is dependent on previous generations. Immediate family members are likely to have similar DNA profiles, but even apparently unrelated members of a population have a shared evolutionary history. Conveying the evidentiary strength of matching DNA profiles, therefore, requires the use of both probability and genetics.

Probability

Although the term probability features prominently in describing DNA evidence, the meaning of the term is often left unclear. Indeed, there are several possible approaches to defining probability. A classical definition is based on the notion of the proportion of times an event will occur in repeated opportunities for occurrence. When the probability that a well-shuffled deck of cards will have an ace on top is said to be 1 in 13, there is an implicit understanding that the event will be seen in one-thirteenth of any number of shufflings of the deck. When a weather forecaster says there is a 70% probability of rain that day, the meaning is less clear. Maybe the current conditions have led to rain in 70% of previous occasions, but the listeners will need to make a decision about taking an umbrella based on their understanding of this figure. The personal element is even more clear in a courtroom when a prosecutor asks a jury to convict the defendant because the probability of guilt is so high as to be beyond reasonable doubt. The probabilities attached to DNA profiles cannot be interpreted as population proportions when they are very much smaller than one over the population size. They might be interpreted as personal measures of uncertainty, or they might be explained as being the result of a set of prescribed calculations. Even such calculations, however, necessarily have some subjectivity on the part of the person performing the calculations.

Laws of Probability

However probability is defined, it must obey a set of rules in order to be useful. Suppose there is interest in some event H : that the card on top of a well-shuffled deck is an ace, or that it will rain today, or that the defendant is guilty. There is some information I about the event: the deck has four aces among the 52 cards, or the weather forecaster is very good, or the evidence against the defendant is very strong. The probability of H , given the information I , is written as $\Pr(H|I)$, and it satisfies the three 'Laws of Probability.'

The first law says that probabilities are numbers between zero and one (inclusive) and that the probability of a certain event is one. In symbols,

$$0 \leq \Pr(H|I) \leq 1 \\ \Pr(H|H) = 1$$

The second law says that the probability of either of two mutually exclusive events G , H happening is the sum of the separate probabilities for G and H . In the card example, the events G : 'The face card is a king' and H : 'The face card is an ace' are mutually exclusive because they cannot both occur. Likewise, 'rain' and 'no rain' or 'the defendant is the source of DNA' and 'the defendant is not the source of the DNA' are pairs of mutually exclusive events. In symbols,

$$\Pr(G \text{ or } H|I) = \Pr(G|I) + \Pr(H|I)$$

From the first law, this implies that the probability of the defendant either being the source of a DNA sample or not being the source, given the evidence, is one.

The third law gives the probability of both of two events, G and H , occurring. The joint probability is the probability that the first of them occurs multiplied by the probability of the second given that the first has occurred. The 'first' and 'second' labels are arbitrary; so, symbolically,

$$\Pr(G \text{ and } H|I) = \Pr(G|I) \Pr(H|G, I) \\ = \Pr(H|I) \Pr(G|H, I)$$

For the card example, suppose G is 'The top card is a face card' and H is 'The top card is an ace.' For a standard deck of cards:

$$\Pr(G|I) = 16/52 \quad \Pr(H|G, I) = 1/4 \quad \Pr(G \text{ and } H|I) = 1/13 \\ \Pr(H|I) = 1/13 \quad \Pr(G|H, I) = 1 \quad \Pr(H \text{ and } G|I) = 1/13$$

If the knowledge of one event having occurred does not affect the probability of another event, the two events are said to be independent. When events G , H are independent:

$$\Pr(G \text{ and } H|I) = \Pr(G|I)\Pr(H|I)$$

Bayes' Theorem

The laws of probability can be used to derive a result that is central to the interpretation of DNA evidence. From the third law, for any two events G , H ,

$$\begin{aligned}\Pr(H|G, I) &= \frac{\Pr(H \text{ and } G|I)}{\Pr(G|I)} \\ &= \frac{\Pr(G|H, I) \Pr(H|I)}{\Pr(G|I)}\end{aligned}$$

The second expression is the simplest form of ‘Bayes’ theorem,’ and it allows for the probability of an event given a second event to be expressed in terms of the probability of the second event given the first. In other words, there has been a transposing of the condition from $H|G$ to $G|H$. This transposition requires knowledge of the separate probabilities of G and H .

The law can be written in an ‘odds form’ by rewriting it for the event $\bar{H}$: ‘not H ’

$$\Pr(\bar{H}|G, I) = \frac{\Pr(G|\bar{H}, I) \Pr(\bar{H}|I)}{\Pr(G|I)}$$

and then dividing the first expression by the second

$$\frac{\Pr(H|G, I)}{\Pr(\bar{H}|G, I)} = \frac{\Pr(G|H, I)}{\Pr(G|\bar{H}, I)} \times \frac{\Pr(H|I)}{\Pr(\bar{H}|I)}$$

The probability of an event divided by the probability of not that event is called the odds, so $\Pr(H|I)/\Pr(\bar{H}|I)$ is the ‘prior odds’ of H , that is, the odds prior to knowledge of event G . After the acquisition of knowledge that event G has occurred, the ratio $\Pr(H|G, I)/\Pr(\bar{H}|G, I)$ is the ‘posterior odds’ of H . In equation form,

$$\text{Posterior odds} = \text{LR} \times \text{Prior odds}$$

where the ratio of the two conditional probabilities $\Pr(G|H, I)$ to $\Pr(G|\bar{H}, I)$ has been termed the ‘likelihood ratio’ (LR).

Forensic Probabilities

This formal language of probability theory has an immediate application for the interpretation of DNA evidence. Although the ultimate question in a trial concerns the guilt or innocence of the defendant, attention here is focused on just the DNA evidence. A common situation is where DNA is recovered from a biological sample left at the scene of a crime, and there is reason to believe the sample is from the perpetrator of the crime. DNA is also extracted from a blood or saliva sample from a suspect in the crime and is found to have the same profile as the crime sample. The events G and H are

G : The DNA profiles of the suspect and crime sample (are the same).

H : The crime sample is from the suspect.

$\bar{H}$: The crime sample is not from the suspect.

I : Other information relevant to the probabilities of G and H .

If the suspect is charged with being the perpetrator and becomes the defendant in a trial, the court is going to be interested in the probability of the defendant being the perpetrator given the evidence of a DNA match. Bayes’ theorem makes it clear that this can be calculated only if some prior probability can be assigned. An extreme view might be that, prior to the DNA evidence, the defendant had the same probability ($1/N$) as anyone else in the population of being the perpetrator. For a population of size N , the prior odds would

be $(1/N)/[1-(1/N)] = 1/(N-1) \approx 1/N$. The posterior odds would be LR/N .

It is not customary to present prior odds in criminal trials, although they are routinely used in civil paternity disputes. For that situation, it is customary (if illogical) to assume the alleged father has a 50% probability of being the father before DNA evidence is collected. The prior odds are then one, and the posterior odds are the same as the LR, which is known as the ‘Paternity Index.’ In criminal trials, the problem of assigning odds can be avoided by presenting only the LR, and the forensic scientist can testify that

The DNA evidence (G) is LR times more likely if the defendant is the source of the crime sample (event H) than if some other person is the source of the crime sample (event $\bar{H}$).

DNA Likelihood Ratios

Calculation of the LR is clarified by considering the nature of the DNA evidence G in some more detail. The evidence can be considered to be the events that profiles G_C of the crime sample and G_S of the suspect are both of type $\mathcal{A}$,

$$G : G_C = \mathcal{A} \text{ and } G_S = \mathcal{A}$$

From the third law of probability,

$$\begin{aligned}\Pr(G|H, I) &= \Pr(G_C = \mathcal{A} \text{ and } G_S = \mathcal{A}|H, I) \\ &= \Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, H, I) \Pr(G_S = \mathcal{A}|H, I) \\ \Pr(G|\bar{H}, I) &= \Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, \bar{H}, I) \Pr(G_S = \mathcal{A}|\bar{H}, I)\end{aligned}$$

So the LR is

$$\text{LR} = \frac{\Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, H, I)}{\Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, \bar{H}, I)} \times \frac{\Pr(G_S = \mathcal{A}|H, I)}{\Pr(G_S = \mathcal{A}|\bar{H}, I)}$$

Now the DNA profile of the suspect was determined at the moment of conception of that person and cannot be influenced by whether or not the person left the crime sample, so $\Pr(G_S = \mathcal{A}|H, I) = \Pr(G_S = \mathcal{A}|\bar{H}, I) = \Pr(G_S = \mathcal{A}|I)$. The LR reduces to

$$\text{LR} = \frac{\Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, H, I)}{\Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, \bar{H}, I)}$$

Further simplification follows from the assumption that the DNA typing system is sufficiently reliable and that two samples from the same person will be found to match. When the suspect is the perpetrator (event H), the crime sample must therefore be of type $\mathcal{A}$ if it is known that the suspect is of type $\mathcal{A}$, so $\Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, H, I) = 1$ and

$$\text{LR} = \frac{1}{\Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, \bar{H}, I)}$$

A final simplification follows from assuming that the DNA profiles from two different people (the perpetrator and the suspect when $\bar{H}$ is true) are independent, so $\Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, \bar{H}, I) = \Pr(G_C = \mathcal{A}|I)$, and

$$\text{LR} = \frac{1}{\Pr(G_C = \mathcal{A}|I)}$$

This last equation is the initial way DNA evidence was presented. Only the probability with which an unknown person

would have the profile is needed. The information I may contain information about the population to which that person belongs. A profile probability of one in a million can be regarded as giving an LR of 1 million. The evidence would be 1 million times more likely if the suspect is the source of the DNA than if some other person is the source.

It needs to be stressed that the results in this section apply only to the situation where the DNA evidence refers to material left at the crime scene by the perpetrator, and there is no DNA evidence at the scene that does not provide a match to the profile of the suspect. If the evidence refers instead to a bloodstain found on the clothing of the suspect, for example, and the stain has a DNA profile matching that of the victim, then additional factors need to be considered: What is the probability that the victim's blood would be transferred during the crime? What is the probability that the suspect would have non-self blood on his or her clothing? What is the probability that non-self blood on the suspect's clothing would match that of the victim?

Nature of DNA Profiles

To quantify the evidentiary strength of a matching DNA profile, it is necessary to decompose the profile into its component parts. DNA profiling examines the two 'alleles' a person receives, one from each parent, at a number of 'loci.' There are several possible allelic types at each forensic short tandem repeat (STR) locus, and a person may have two copies of the same type and so be homozygous at a locus, or may have two different alleles and so be heterozygous. As an example, consider the collection of STR loci used by CODIS. For locus TPOX, the population proportion for the 9, 10 genotype is estimated as $2p_{9\text{TPOX}}p_{10\text{TPOX}}$, where $p_{9\text{TPOX}}$ and $p_{10\text{TPOX}}$ are the frequencies of TPOX alleles 9, 10. For locus FGA, the proportion for the 19, 19 genotype is $p_{19\text{FGA}}^2$, where $p_{19\text{FGA}}$ is the frequency of FGA 19 alleles. At each locus, these products estimate the probability with which a random person in the population would have that 'genotype.' It has been assumed that the two alleles received by an individual at one locus are independent. To combine information over loci, it is further assumed that alleles at different loci are independent, and the products for each locus are multiplied together. For the two-locus profile in this example, the 'product rule' calculation gives

$$\Pr(G_C = \mathcal{A}|I) = 2p_{9\text{TPOX}}p_{10\text{TPOX}}p_{19\text{FGA}}^2$$

Dependent Profiles

For a crime in which it is known that the perpetrator must have a DNA profile of type $\mathcal{A}$ because the evidentiary sample had that type, it is natural to consider the profile probability, that is, the probability of a random person in the population having that type. This is the quantity $\Pr(G_C = \mathcal{A}|I)$ given at the end of the previous section. However, the evidential value of the sample needs to take into account the fact that there is a person (the defendant) who has already been seen to have that profile. The quantity of forensic interest is the match probability, that is, the conditional probability $\Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, \bar{H}, I)$, and this can be quite different from $\Pr(G_C = \mathcal{A}|I)$.

Table 1 Effects of family relatedness

Genotype $\mathcal{A}$	Relationship	$\Pr(G_C = \mathcal{A} G_S = \mathcal{A}, \bar{H}, I)$	LR
$A_i A_j$	Full sibs	$(1 + p_i + p_j + 2p_i p_j)/4$	3.3
	Parent and child	$(p_i + p_j)/2$	10.0
	Half sibs	$(p_i + p_j + 4p_i p_j)/4$	16.7
	Uncle and nephew ^a	$(p_i + p_j + 4p_i p_j)/4$	16.7
	First cousins	$(p_i + p_j + 12p_i p_j)/8$	25.0
	Unrelated	$2p_i p_j$	50.0
$A_i A_i$	Full sibs	$(1 + p_i)^2/4$	3.3
	Parent and child	p_i	10.0
	Half sibs	$p_i(1 + p_i)/2$	18.2
	Uncle and nephew ^a	$p_i(1 + p_i)/2$	18.2
	First cousins	$p_i(1 + 3p_i)/4$	30.8
	Unrelated	p_i^2	100.0

^aOr uncle and niece, aunt and nephew, aunt and niece.

Effect of relatives

The largest effect of dependencies between the DNA profiles of two people is when they are related. Relatives have the possibility of receiving the same genetic material from their common ancestors and, therefore, of having the same DNA profile. Some common values for the conditional probabilities are shown in Table 1, where p_i is the population frequency of allele A_i . To put the effect into perspective, numerical values of $LR = 1/\Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, \bar{H}, I)$ are shown for the situation when all alleles have a frequency of 0.1. The effects of relatives are less for larger frequencies; but in all cases, the LRs are reduced when the alternative to the suspect being the DNA source is that a relative of the suspect is the source.

Effect of population structure

If a locus has five alleles, there are 15 possible pairs of alleles, or genotypes, at the locus. For 10 such loci, the number of possible genotypes is 576 billion. The number of possible profiles greatly exceeds the size of the world population, and the profile probability of any profile is small. However, the match probability is greater than the simple product rule calculation after that profile has been seen once already. This is because of the dependency among profiles imposed by evolution. Individuals C and S may share a DNA profile simply because they belong to a finite population. Although they may not be in the same family, they each have (at most) 2^n ancestors n generations ago, and this number quickly exceeds the population size. Any two people may have some ancestors in common, and this leads to a non zero probability of shared profiles. This probability is greater for smaller populations.

The theory currently used by forensic scientists to accommodate this evolutionary perspective rests on the following argument. If the allele frequencies in a subpopulation are known, the probability of an unknown person C having a certain DNA profile is estimated by the product rule using those allele frequencies. This calculation does not use the knowledge that S has already been seen to have the profile. However, the usual situation is that allele frequencies are not available for the subpopulation. This may be for practical difficulties in taking a sample from that group, or it may be because the subpopulation is not well defined. Instead, allele frequencies are available

Table 2 Effects of population structure

		Likelihood ratio			
		$\theta = 0$	$\theta = 0.001$	$\theta = 0.01$	$\theta = 0.03$
$p = 0.01$	Heterozygote	5000	4152	1295	346
	Homozygote	10 000	6439	863	157
$p = 0.05$	Heterozygote	200	193	145	89
	Homozygote	400	364	186	73
$p = 0.10$	Heterozygote	50	49	43	34
	Homozygote	100	96	67	37

(or can be estimated) for the whole population. Taking an average over subpopulations of the conditional probability $\Pr(G_C = A | G_S = A, \bar{H}, I)$ leads to the following single-locus results for homozygotes $A_i A_i$ or heterozygotes $A_i A_j$,

$$\Pr(G_C = A_i A_i | G_S = A_i A_i, \bar{H}, I) = \frac{[2\theta + (1 - \theta)p_i][3\theta + (1 - \theta)p_i]}{(1 + \theta)(1 + 2\theta)}$$

$$\Pr(G_C = A_i A_j | G_S = A_i A_j, \bar{H}, I) = \frac{2[\theta + (1 - \theta)p_i][\theta + (1 - \theta)p_j]}{(1 + \theta)(1 + 2\theta)}$$

In these equations, θ is a measure of population structure. It can be considered as a measure of the variability of allele frequencies over subpopulations: the variance of the frequency of A_i over subpopulations is $\theta p_i(1 - p_i)$. It is also a measure of the relatedness of two alleles in the same subpopulation, the probability that two alleles in a subpopulation have a single ancestral allele. Some numerical consequences of allowing for population structure are shown in [Table 2](#), where all alleles have the same frequencies p .

One of the difficulties with this theory is in assigning a value to θ . If observations were available from a series of subpopulations within a population, it is possible to estimate $(\theta - \phi)/(1 - \phi)$ where ϕ is the probability that two alleles in the whole population have a single ancestral allele. The quantity ϕ is often assumed to be zero, so that it is θ being estimated from subpopulation data. However, it is the lack of subpopulation data that has made the ' θ -formulation' necessary in the first place, and the usual procedure is to assign a value, such as 0.03, to θ . It needs to be stressed that the equations apply on average for any subpopulation within the population.

Database Searches

There are now many large-scale databases of forensic DNA profiles, including those used by CODIS. These may be used to search for possible perpetrators or their relatives in cases where there are no suspects or to seek evidence for links between different crimes. They could also be used to validate the statistical procedures used in this discussion.

Within-database comparisons

A database of 2000 (or 2 million) profiles allows for comparisons to be made between a million (or a trillion) pairs of profiles. Rare events may therefore be found, including the event that two profiles are found to match. The matching is for any profile, as opposed to a prespecified particular profile, and this is an illustration of the 'birthday problem' which states there is greater than 50% chance of finding two people in a

group with the same birthday once the group size exceeds 23. The chance that two people will have a particular birthday is much smaller. This logic leads to the prediction that it is virtually certain that there are two people in the United States with the same 13-locus STR profile.

Cold-hit interpretation

When suspects are identified because their profiles in a database are found to match a crime-scene profile, there has been a suggestion that the strength of the DNA evidence should be down-weighted. If the database has 1 million profiles, an LR of 1 billion should be reduced to 1000 (1 billion divided by 1 million). The probability of finding a match will certainly increase as the database size increases and, indeed, finding a match is certain once the database includes the profiles of everyone. Although the prior probabilities that suspects identified by database searches change with database size, the LRs expressing the strength of the DNA evidence against the suspect (s) so identified are not changed by the size of the database.

Familial searching

If a database profile is very similar to, but not exactly the same as, a crime-scene profile, the possibility that it is from a close relative of the perpetrator is raised. Such familial searching has led to some successes in the cases of parent–offspring and full-sibling relationships. Familial searches can be guided by LRs that compare the probability of a database profile if it was from a relative of specified degree to the source of the query profile (using the equations in [Table 1](#)) to the probability that it was from a person unrelated to the source. Difficulties arise because the LRs may be higher by chance for those not related than for true relatives, and high stringency levels are needed to avoid the need to investigate large numbers of false positives.

Familial searching is analogous to remains identification, for example, after mass disasters such as the World Trade Center bombings.

Conclusion

The interpretation of matching DNA profiles often relies on some statements of probability. These statements refer to the chance of an unknown person having the profile given that a known person has been seen to have the same profile. A simple approach is to ignore the conditioning on the known person and use an estimate of the population frequency of the profile. However, this ignores the possibility that the known and

unknown persons are related either by being in the same family or by being in the same population.

Glossary

Conditional probability One of the terms needed for probability calculations using Bayes' theorem, normally the likelihood ratio calculated from genetic test results.

Deficiency case Term used to describe a parentage test which lacks a known parent.

Likelihood ratio The numerical statement of the weight of the evidence favoring the opinion that the alleged parent is the true parent of the child.

Maternity index The name given to the likelihood ratio produced in a case of questioned maternity.

Obligate allele An allele observed in a child that had to be inherited from the parent whose identity is in question.

Paternity index The name given to the likelihood ratio calculated in a case of questioned paternity.

Posterior probability The probability produced using Bayes' theorem reflecting the level of certainty that an included alleged parent is the true parent of a child.

Prior probability A term incorporated into Bayes' theorem that reflects the probability of parentage that existed before genetic testing was performed.

VNTR The term used to describe hypervariable genetic markers consisting of short sequences of tandemly repeated nucleotides in chromosomal DNA.

History of Parentage Testing

The first documented case of disputed parentage can be found in the Old Testament in Kings I, Chapter 3, verses 16–27 in the story of King Solomon. Two women in a household gave birth to children at about the same time and one child died. The mother of the child who died switched her dead child for the living child while its mother slept and then claimed the living child as her own. When faced with adjudicating this case, Solomon ordered the living child to be cleaved in half and each mother to be given one half of the child. The true mother, hearing the King's ruling, begged the King not to kill her child but rather to rule the thieving mother to be the child's true parent, thereby sparing its life. Solomon accepted the woman's plea but ruled she was the child's true mother and ordered the thief to be put to death.

Parentage testing has changed significantly since the time of King Solomon. Judges do not order children to be halved or alleged parents to be punished by death. More appropriately, decisions regarding the true parentage of a child incorporate the results of genetic marker testing considered within the framework of Mendel's laws in deciding whose is and who is not the true parent of a child.

The field of parentage testing began in the 1950s and 1960s with the analysis in paternity trios of red blood cell antigens as genetic systems that were well characterized, could be detected with readily available serological reagents, and were routine tests performed in blood banks around the country. Because of the rather weak discriminatory power associated with testing for red cell antigens of the ABO, MN, and Rh systems, blood typing had as its goal, at that time, the exclusion of an alleged father who was falsely accused.

The widespread use of genetic testing in matters of disputed parentage expanded during the 1960s and 1970s due to a dramatic rise in illegitimacy. During this 10-year period, about 1.7 million children were born out of wedlock. In

addition to the absolute number of illegitimate children born during this period, the rate of illegitimacy was increasing, thus further exacerbating the problem. One significant social consequence of the rise of illegitimacy was a financial strain on the welfare program aid to families with dependent children (AFDC) designed to provide war widows with additional income to help support their dependent children. The dramatic rise in single-parent families due to delinquent fathers, together with a general feeling that a child has a need and right to a legal relationship with his/her father, led to the enactment of the Child Support Enforcement Act in 1974 which aimed to reduce welfare costs by collecting support for families from delinquent parents, and to also impose family responsibility.

Paralleling the social/legislative developments surrounding disputed parentage was the discovery in the 1970s of the HLA antigen system and the development of routine tissue typing methods. For the first time, it was not only possible to exclude a high proportion of falsely accused men (~98%), but the discriminatory power of the HLA antigen system afforded labs the possibility of calculating probabilities of paternity for men who could not be excluded as fathers in paternity suits. With the wider use of testing, the need for standardization in the field was formally recognized by the American Medical Association and the American Bar Association. The American Association of Blood Banks (AABB), the organization representing the blood banks and transfusion services in which much of the testing for parentage was performed, also recognized the need for standardization in the field. In recognition of this need, a Committee on Parentage Testing was formed in 1978 and tasked with cultivating a consensus among experts that could form the basis for an accreditation program. In 1984, an accreditation program for parentage testing labs was initiated by the AABB. In 2009, the 9th edition of the *Standards for Parentage Testing Laboratories* was published by the AABB, reflecting the ever-changing technology associated with the field.

Technical Considerations

Two technological advances have had dramatic impact on the field of parentage testing. One, HLA testing, was principally responsible for the evolution of inclusionary statistical calculations associated with testing. The second major advance came in the mid-1980s with the discovery of hypervariable DNA polymorphisms that could be revealed using restriction fragment length polymorphism (RFLP) analysis. VNTR loci, visualized using RFLP methods, exhibited levels of polymorphism comparable to the HLA system and had other advantages as well. One advantage was that the scope of acceptable sample types was broadened. No longer was freshly procured blood an absolute must for testing as in the case of HLA typing. Blood stains, tissue samples, and even buccal swabs could now be used as a source of material for testing. Second, a single Southern blot of restricted DNA from a parentage trio could be sequentially hybridized to multiple probes detecting different VNTR loci, producing a very powerful test battery for the relationship in question. This advantage over other genetic testing technologies was perhaps the main driving force promoting the use of DNA typing among labs.

In 1992 with the publication of the 2nd edition of the *Standards for Parentage Testing Laboratories*, the AABB officially recognized the value and widespread use of DNA typing in the field and the first labs became accredited to this technology. Thus, RFLP analysis for questioned parentage was the first DNA typing technology to be covered under an accreditation program. Soon to follow were standards and accreditation for the analysis of small tandem repeat (STR) loci. By 2002, 90% of labs reported using STR typing as their principal technology, a testament to the efficiency and effectiveness of STR versus RFLP analyses for performing testing in a cost-effective manner.

The Methods Used in Parentage Testing

The STR typing methods in widespread use among parentage testing laboratories are essentially those used by forensic DNA typing laboratories to produce profiles from reference or convicted felon samples. The most commonly obtained samples are buccal swabs, although, in some cases, 'forensic type samples' must be used as a source of DNA for analysis. Such cases include products of conception in rape cases and bone for labs engaged in the identification of human remains. Labs may also occasionally be asked to identify the source of evidentiary samples recovered in missing person cases through family relatedness analysis.

Extraction of DNA from the typical parentage samples follows extraction methodologies that are widely used in forensic labs. Special sample types such as bone require additional steps such as pulverization and demineralization; however, ultimately standard DNA extraction methods are applied to the pretreated samples to liberate and recover DNA present. Once DNA has been recovered, quantitation may be required, although, when dealing with buccal swabs collected from normal healthy individuals, quantitation is often not necessary because of the predictability of DNA recovery using some extraction technologies.

Recovered DNA is then subjected to amplification of a collection of STR loci targeted in currently available multiplex STR typing kits such as Identifiler (Applied Biosystems, Inc., Foster City, CA) or Powerplex 16 (Promega Corp., Madison, WI). These multiplex kits provide a very high discriminatory power for parentage testing applications (Table 1).

In a recent publication from Hill et al., an STR multiplex was described that co-amplified 26 STR loci simultaneously. While at first blush this might seem to be overkill, establishing or refuting family relationships when the only individuals available for testing are distantly related can be problematic and require more loci to be examined.

Amplified STR products, once produced, are generally separated by size using a capillary electrophoresis platform that is part of a genetic analyzer. Inasmuch as the process for producing electropherograms is the same for parentage testing as for forensic DNA testing, it will not be discussed here. Instead, data analysis in scenarios involving questioned parentage is the focus of this discussion and differs significantly from the typical analysis performed in the forensic DNA laboratory.

Analysis of the Typical Parentage Trio

Perhaps the most commonly encountered scenario in parentage testing involves a trio of individuals – a known parent of the child, the child, and an alleged parent. Often, this scenario will involve questioned paternity and the testing will be initiated by a mother or the state, both of whom want to compel the father to help provide financially and emotionally for the child.

Table 1 Discriminatory power associated with STR loci in the Identifiler multiplex kit

<i>Discriminatory power associated with common multiplex kits^a</i>		
<i>Locus</i>	<i>Prob. of identity^b</i>	<i>Prob. of exclusion^c</i>
CSF1PO	0.119	0.475
D2S1338	0.033	0.636
D3S1358	0.111	0.557

D21S11	0.051	0.608
FGA	0.033	0.644
TH01	0.105	0.581
TPOX	0.151	0.482
VWA	0.079	0.604
Cum. values	$\sim 2 \times 10^{-18}$	>99.99%

^aNumbers shown represent averages across the major population groups (i.e., white, black, hispanic, and native American). The 15 STR loci shown below are all co-amplified along with the amelogenin locus as members of the AmpflSTR Identifiler® multiplex DNA typing kit (Applied Biosystems, Foster City, CA).

^bThe chance two unrelated individuals, selected at random from the population, would have the same STR phenotype for the locus in question.

^cChance of excluding a randomly selected individual as the parent of a child, when the known parent is also tested. Exclusion probabilities will decrease significantly in one parent cases.

The typical trio is also the most straightforward to analyze statistically because each member has been tested and the collection of genetic markers can, therefore, be compared directly. Mendel's laws require half of the alleles in the child's sample to be traceable to each true parent. Thus, one allele in the child's profile for a given marker must match an allele in the known parent, which allows the other allele in the child's profile to be compared directly with the collection of alleles detected in the alleged parent's DNA. The title 'known parent' also defines the assumptions used in the statistical analysis of results leading to the calculation of a likelihood ratio (LR) in an inclusion case that reflects the weight of the evidence favoring the alleged parent as the true parent of the child. The LR may be called many things including paternity index (in cases of questioned paternity), maternity index (in cases of questioned maternity), sibling index (in cases of questioned sibship), etc. The reader should understand, however, that in each case, the term refers to an LR that is a numerical statement of weight regarding the questioned relationship.

Consider the following pedigree and STR test results in the case of disputed paternity:

Locus	STR	Phenotypes	M
	AF	C	
D8S1179	12,14	10,12	10,13
D21S11	29,32.2	29	29,30
D7S820	12	10,12	10,12

STR typing results for three loci reflecting different states of zygosity and allele sharing in the trio are shown. The alleged parent shares at least one allele with the child at each locus and, moreover, the allele shared is one of the possible obligate alleles for each marker. For example, at the D8S1179 locus, the known parent (the mother in this case) shares allele 10 with the child. Based upon the assumption that the known parent is a true parent, allele 12 must, therefore, have been inherited from the parent whose identity is questioned. The alleged parent has allele 12 in his profile and, therefore, is included among a pool of possible parents. In assigning weight to the inclusion, two hypotheses will be compared to calculate the LR: H0 and H1. H0 estimates the likelihood or probability of the alleged parent:child:known parent trio, if the alleged father is the true father of the child, that is, the chance of producing a child who looks like this child through a mating of the alleged father with the mother. Since the mother is heterozygous, her chance of passing allele 10 to a child is 50% or 0.5. Likewise, since the alleged father is heterozygous, his chance of passing allele 12 to the child is also 0.5. If either the AF or M were homozygous for an obligate allele in the child, their chance of allele transmission would double from 0.5 to 1.0. The probability of the mother passing allele 12 is zero as is the probability of the alleged father passing allele 10. Therefore,

$$H0 = (0.50_{\text{Allele 10 from Known Parent}}) (0.50_{\text{Allele 12 from Alleged Parent}}) + (0_{\text{Allele 12 from the Known Parent}}) (0_{\text{Allele 10 from the Alleged Parent}}) = 0.25$$

The counterhypothesis (H1) predicts the likelihood of the results if the alleged parent is not the true parent of the child, that is, the probability of producing a child who looks genetically like this child through a mating of the mother with an unknown, untested, random man of the same ethnicity as the alleged father. This random man must harbor allele 12 in his profile (because allele 12 is the obligate allele) and his probability of transmitting allele 12 to the child is defined by its population frequency. If allele 12 has a frequency of 0.097 and allele 10 a frequency of 0.140, then

$$H1 = (0.50_{\text{Allele 10 from Known Parent}}) (0.097_{\text{Allele 12 from RM}}) + (0_{\text{Allele 12 from Known Parent}}) (0.140_{\text{Allele 10 from RM}}) = 0.0485 \text{ (where RM is the 'Random man')}$$

The LR for the D8S1179 test result thus becomes a mathematical comparison of the probabilities of the H0 and H1 hypotheses:

$$LR = H0/H1 = 0.25/0.0485 = 5.16$$

Given the test results observed at the D8S1179 locus, the results are a little over five times as likely if the alleged parent is the true parent of the child versus someone unrelated to the alleged parent, of the same ethnic group, and random in the population. Stated perhaps more meaningfully, the probability of producing a 10, 12 child from a mating of the alleged and known parent is favored by a factor of 5.16-fold over the probability of producing the child from a mating of the known parent with a randomly selected, untested, and unrelated individual of the same ethnic background.

Locus	D21S11	Phenotypes	M
	AF	C	
D21S11	29,32.2	29	29,30

Consider the test results for the D21S11 locus:

The mother shares allele 29 with the child (who is homozygous for allele 29), defining another copy of allele 29 in the child's homozygous profile as the obligate allele for the locus. The two hypotheses being compared for the D21S11 locus are identical to those expressed above and both the mother and alleged father are heterozygous for allele 29. The fact that the child is homozygous for the obligate allele will have no bearing on the calculation. The LR calculation thus becomes (assuming allele 29 has a frequency of 0.205):

$$\begin{aligned} LR &= H0/H1 \\ LR &= [(P_{M-29})(P_{AF-29})]/[(P_{M-29})(P_{RM-29})] \\ LR &= [(0.5)(0.5)]/[(0.5)(0.205)] \\ LR &= 0.25/0.1025 = 2.44 \end{aligned}$$

Locus	D7S280	Phenotypes	M
	AF	C	
D7S280	12	10,12	10,12

Consider the results for the D7S820 locus. The results for D7S820 introduce us to a new layer of complexity, that is, that the allele inherited by the child from the mother is unclear. In addition, the alleged father is homozygous for allele 12 which means his probability of transmitting it doubles to 100%.

To calculate the LR for D7S820, one must consider both possible transmissions of alleles from the mother to the child. Likewise, in the denominator (i.e., the H1 hypothesis), one must consider possible matings of the mother with random men capable of transmitting either allele 10 or allele 12 to the child. Therefore, the LR calculation becomes (assuming the allele frequency for allele 12 is 0.140 and that for allele 10 is 0.291)

$$\text{LR} = \frac{[(0.5_{M-10})(1.0_{AF-12}) + (0.5_{M-12})(0_{AF-10})]}{[(0.5_{M-10})(0.140_{RM-12}) + (0.5_{M-12})(0.291_{RM-10})]}$$

$$\text{LR} = 0.5/0.2155 = 2.32$$

Now that the individual LR for each locus has been calculated, all the data can be combined since ultimately one is evaluating whether or not the alleged parent is capable of producing a single gamete (sperm or egg) capable of transmitting all of the necessary genetic markers to the child. Because each STR locus analyzed is independently inherited, each LR can be multiplied by every other LR to arrive at a combined value. The goal is to achieve a level of certainty regarding parentage that is compelling. Accreditation standards for parentage testing laboratories issued by the AABB (9th edition) mandate a combined LR of at least 100 as the threshold of certainty that must be achieved, except in special circumstances.

In addition to calculating an LR, it is possible to evaluate the test results from the perspective of the random match probability typically calculated by the forensic DNA laboratory. The statistic calculated is called the RMNE (which stands for random men not excluded) and simply reflects the chance of selecting someone at random from the population and being unable to exclude them as the parent of a given child. In addition to the RMNE, the probability of exclusion (PE_x) for a locus or combination of loci can be calculated which reflects the discriminatory power of a given test or group of tests. Simply stated, the PE_x is the probability the alleged parent would have been excluded, if they were falsely accused. To calculate PE_x, one must first calculate the RMNE value. This, as might be expected, is proportional to the population frequency of the obligate allele(s) identified in the child. For the D8S1179 locus for example, the obligate allele is 12, which has a population frequency of 0.097. To calculate the proportion of the population harboring allele 12 who would be included as a potential parent of the child (i.e., the RMNE), the Hardy-Weinberg equation is used to estimate homozygous and heterozygous phenotypes containing allele 12:

$$p^2 + 2pq = (0.097^2) + 2[(0.097)(1 - 0.097)] = 0.185$$

(The '1-0.097' term in the equation represents the combined frequency of all other alleles at the D8S1179 locus, except allele 12.)

Thus, 18.5% of the population would be expected to harbor allele 12 and, therefore, be included as a possible parent of the child. In an extension of this logic, 100% of people minus those who would be included leave a remainder of individuals

who would not have allele 12 in their profile and, therefore, be excluded. In this case, 81.5% of the population would be excluded which represents the PE_x for the D8S1179 locus in this case. Of special note is the fact that the PE_x value is calculated ignoring the genotype of the alleged parent. The only information needed to calculate PE_x is the identity of the obligate gene in the child, deduced by comparing the profiles of the child and known parent.

Early in the use of inclusionary statistics for parentage testing, some states considered the PE_x value alone for the determination of parentage. For example, legislation supporting child support enforcement activities in some states mandated that any man not excluded by a battery of genetic tests that excluded at least 95% of the population would be deemed by the state to be the true father of the child. While this approach may seem at first glance acceptable, it does not consider the phenotypes of possible fathers of the child. Both an alleged father who is heterozygous for an obligate allele and one who is homozygous would have the same PE_x value when clearly an alleged parent homozygous for an obligate allele would transmit it to children with twice the frequency of a heterozygote.

In addition to reporting LR values in parentage cases, a probability of parentage must appear on reports from accredited labs. The probability of parentage is another way to express the weight of the evidence supporting the opinion of parentage and is calculated using Bayes' theorem. Bayes' theorem, simply defined, allows for the combining of genetic and nongenetic information relevant to questioned parentage into a final statement of probability. Three terms are incorporated into Bayes' formula: the prior probability, the conditional probability, and the posterior probability. In matters of questioned relatedness, the level of certainty of the relationship, before genetic testing is performed, represents the prior probability. The prior may include evidence that the alleged and known parent were living together and acknowledged publicly that they had a sexual relationship during the period of conception. Following genetic testing however (representing the conditional probability), if the alleged parent is excluded, the level of certainty regarding parentage will be modified downward (i.e., one will be less convinced if the alleged parent represents the true parent of the child). The combination of the prior and conditional probabilities (represented by the LR) produces the posterior probability, reflecting the revised level of certainty regarding the relationship after incorporating the new information.

The calculation of the posterior probability involves creating a ratio comparing the evidence favoring parentage (under a given prior probability) with the probability both for and against parentage. Assume for this discussion that the alleged parent convinces a judge whether he/she was not in contact with the known parent during the period of conception. The judge could assign a prior probability of 10%. In other words, there is a low probability that the alleged parent is the true parent of the child based upon nongenetic information. The fact that genetic testing did not exclude the alleged parent and, moreover, has produced a combined LR of 100 will surely modify the 10% level of certainty, however. The posterior probability calculation would take the following form:

$$W_{10} = [(0.10_{\text{Prior for}})(100_{\text{LR}})] / [(0.10_{\text{Prior for}})(100_{\text{LR}}) + (0.90_{\text{Prior against}})] = 10/10.9 = 0.917, \text{ or } 91.7\%$$

The term W_{10} refers to the posterior probability calculated using a prior of 10%.

Therefore, a probability of 91.7% reflects the current level of conviction that the alleged parent is the true parent of the child. It must be stressed that the probability reported represents an opinion as evidenced by the fact that it is impossible to produce a probability of parentage equal to 100% for an alleged parent, no matter how much inclusionary genetic testing is performed. Look at what happens to the posterior probability if the judge, knowing that the alleged and known parents were together on a largely uninhabited island during the period of conception, assigns a prior probability of 90%:

$$W_{90} = (0.90)(100) / [(0.90)(100) + (0.10)] = 90/90.1 = 0.9989, \text{ or } 99.89\%$$

Clearly, a much higher level of certainty regarding the parentage of the child is produced under a 90% prior for the same LR of 100. Most relatedness testing labs assign a prior probability of 50% unless instructed by the court to do otherwise. The reason for choosing 50% relates primarily to the neutrality of the lab, basing the posterior probability strictly on the genetic test results alone. The relationship between prior probability and LR is shown graphically (the abscissa reflects the LR calculated and the ordinate reflects the posterior probability of parentage; Figure 1).

Cases Lacking a Known Parent

Often, a lab will be asked to perform relatedness testing in a situation in which a known parent is not available to provide a sample for analysis. The consequence of not having a known parent for the analysis is to typically reduce the LRs for each system tested, often forcing a lab to do more testing to achieve a compelling result. Consider the pedigree and STR test results shown in the table as follows:

Figure 1 Relationship of posterior probability (y-axis) and LR (x-axis), displayed under three different prior probabilities.

Locus	STR	Phenotypes	
	AF	C	M
D8S1179	12,14	10,12	NT
D21S11	29,32.2	29	NT
D7S820	12	10,12	NT

In this scenario, the known parent (the mother) has not been tested, but the alleged parent shares at least one allele with the child at each of the three loci shown and is, therefore, included as a possible true parent. To calculate an LR, both alleles in the child must be considered as possible obligates and in calculating the LR.

The hypotheses compared in the LR are H0 (the probability of producing the child from a mating of the alleged parent and an unknown, random mother) versus H1 (the probability of producing the child from a mating of parents who are unrelated and are both random in the population). For each calculation, one must assign a 'random mother' who is phenotypically related to the child and one must consider her probability of transmitting either obligate allele to the child.

Locus	D8S1179	Phenotypes	
	AF	C	M
D8S1179	12,14	10,12	NT

For the D8S1179 locus for example (the frequencies of alleles 10 and 12 are 0.097 and 0.140, respectively, and RM stands for random man and RMom for random mother),

$$\begin{aligned} \text{LR} &= [(P_{\text{AF-12}})(P_{\text{RMom-10}}) + (P_{\text{AF-10}})(P_{\text{RMom-12}})] / [(P_{\text{RM-12}})(P_{\text{RMom-10}}) + (P_{\text{RM-10}})(P_{\text{RMom-12}})] \\ \text{LR} &= [(0.5)(0.097) + (0)(0.140)] / [(0.140)(0.097) + (0.097)(0.140)] \\ \text{LR} &= (0.0485 + 0) / [(2)(0.140)(0.097)] = 0.0485 / 0.0272 = 1.78 \text{ (LR with Mother = 5.16)} \end{aligned}$$

The LR calculation considers two possible matings between the AF and a random mother, separated by the plus sign in the numerator.

The denominator of the calculation reflects the chance the child was produced by a mating of parents both of whom are random using the same logic.

Note how the H1 expression can be reduced to $2(0.097)(0.140)$ which is the same as the $2pq$ portion of the Hardy-Weinberg equation predicting the frequency of the child's heterozygous phenotype.

Locus	D21S11	Phenotypes	
	AF	C	M
D21S11	29,32.2	29	NT

For the D21S11 locus, the child is homozygous for allele 29. Whereas the zygosity of the child had no consequence for the LR calculation when the mother was tested, in a deficiency case, zygosity does have an effect on the magnitude of the LR. For the D21S11 locus (assuming an allele frequency of 0.205 for allele 29),

$$H_0 = (0.50_{AF-29})(0.205_{RMom-29}) = 0.103$$

$$H_1 = (0.205^2) = 0.042$$

$$LR = 0.166/0.042 = 2.44$$

If one compares the LR in the test lacking the mother with the LR for the test in which she was included, one will notice that the values are the same. This seems contradictory to the statement that tests lacking a known parent will almost always produce LR values that are lower. However, recall that the values are lower due to the ambiguity in the origin of alleles in the child's profile. In the case of the D21S11 results, there is no ambiguity in the origin of alleles since the child is homozygous for allele 29; one copy had to have originated from the untested mother, leaving the second copy as the obligate from the father.

Locus	D7S820	Phenotypes	M
	AF	C	
D7S820	12	10,12	NT

For the D7S820 locus, the alleged father is homozygous for one of the possible obligate alleles in the child's profile and thus the transmission frequency for allele 12 to the child has doubled from 0.5 to 1.0:

$$LR = [(1.0_{AF-12})(0.291_{RMom-10}) + (0.0_{AF-10})(0.140_{RMom-12})] / [(2)(0.291)(0.140)]$$

$$LR = (0.291 + 0)/0.082 = 3.55 \text{ (LR with Mother} = 2.32)$$

Parentage testing can also help identify unknown victims of crime or accident. Consider a skeleton found in an isolated area whose identity is unknown. DNA extracted from the remains could be subjected to STR typing and the results compared with profiles from surviving family members. Consider the following pedigree involving remains from an unknown 'Jane Doe' compared with a husband and wife who have a missing daughter:

Locus	STR	Phenotypes	
	AF	C	AM
D8S1179	12,14	10,12	10,13
D21S11	29,32.2	29	29,30
D7S820	12	10,12	10,12

In this scenario, both parents are alleged so there are no assumptions in the analysis that revolve around a known parent. The H_0 hypothesis would become 'what is the probability of the STR profiles in the alleged parents and Jane Doe if the alleged parents are the true mother and father of Jane Doe?' The H_1 hypothesis becomes 'what is the probability of the STR profiles in the alleged parents and Jane Doe if she is unrelated to BOTH alleged parents and is random in the population?' For the results at the D8S1179 locus,

$$LR = [(0.5_{AM-10})(0.5_{AF-12})] / [(2)(0.097)(0.140)]$$

$$LR = 0.25/0.0272 = 9.19$$

Notice how the numerator has not changed from the typical paternity test in which the mother participated in the testing. What has changed is the H_1 hypothesis which mandates that the remains be unrelated to BOTH the AM and AF and be random in the population, represented by the phenotype frequency for the locus in question.

Locus	D7S820	Phenotypes	AM
	AF	C	
D7S820	12	10,12	10,12

As was the case for the D7S820 results discussed earlier, the AM and C are phenotypically identical and therefore all possible breeding scenarios must be considered in the calculation. The LR calculation takes the following form:

$$LR = [(0.5_{AM-10})(1.0_{AF-12}) + (0.5_{AM-12})(0.0_{AF-10})] / [2(0.291)(0.140)]$$

$$LR = 0.5/0.082 = 6.10$$

Shown below graphically are the LR values for parentage tests in the three scenarios, that is, paternity with a known mother (labeled w/M), paternity without a known mother (labeled wo/M), and parentage with both maternity and paternity alleged (labeled AF and AM). Note how the LR values are generally larger in the remains identification cases because of the change in the H_1 hypothesis in the LR calculation (Figure 2).

Special Types of DNA Testing

In some cases, autosomal STR markers will fail to produce a compelling LR in a questioned relationship. In such cases, analysis of DNA markers with special patterns of inheritance may be informative. Using STR markers located on the Y chromosome (Y-STRs) or single nucleotide polymorphisms associated with mitochondrial DNA (mtDNA), a lab can investigate the familial relatedness of an alleged family member with the male and female family lines, respectively.

Figure 2 Magnitude of LR produced in different parentage test scenarios.

Y-STRs exhibit levels of variability within male members of the population comparable to variability of autosomal STR markers. Multiplex Y-STR typing kits are marketed that amplify as many as 17 STR loci on the Y chromosome. Products amplified from male DNA are compatible with capillary- or gel-based platforms for electrophoretic separation and allele detection, and collectively exhibit high levels of discriminatory power. However, one must remember that the samples being compared must all be from male donors for test results to be obtained. Moreover, the males being compared must allegedly belong to a common male family line. For example, consider the following pedigree for which Y-STR typing is being considered:

In this pedigree, even though males are the source of Y chromosomal DNA being tested, the reference male is the mother's brother and thus will be descended from a different male lineage than the man who is questioned as the father of the child. In such a case, the child will likely exhibit a different linear array of Y-STR alleles (called the haplotype) than his maternal uncle and thus results should not be interpreted as exclusionary.

Consider the following pedigree:

In this case, the paternal uncle will be a suitable donor for testing.

Calculations using Y-STRs are performed using haplotype frequencies rather than individual allele frequencies since the markers are tightly linked on the single Y chromosome. Haplotype frequency databases exist and are available from several sources for use in calculations wherein the LR is calculated by $1/n$, where n equals the frequency of the obligate haplotype in the population.

Whereas Y-STRs are descended along the male line, mtDNA polymorphisms are inherited through the maternal lineage. Regardless of your sex, your complement of mtDNA markers was inherited from your mother. mtDNA polymorphisms are typically single nucleotide substitutions located within two specific regions of the mitochondrial genome known as the D-loop which harbors hot spots for SNP-type variability.

Like Y-STRs, mtDNA polymorphisms are defined as haplotypes containing SNP polymorphisms that vary from a reference sequence originally obtained at Cambridge University in the United Kingdom that was arbitrarily chosen as the benchmark sequence to which all other sequences are compared. Also akin to Y-STRs, consideration must be given to carefully select family reference samples allegedly within the maternal lineage. When compared to STR typing, both on the Y chromosome and among autosomal loci, mtDNA is much less powerful for relationship testing.

Mutations and How to Deal with Them

About once in every 500–1000 parentage tests, an isolated result inconsistent with parentage will be encountered. Such inconsistencies occur in the face of overwhelming additional testing that provides a compelling probability that the alleged parent is the true parent of the child. The high degree of variability exhibited by STR loci derives from a somewhat high level of genetic instability and their predisposition to being mis-replicated during meiosis. Ultimately, such mis-replication events produce gametes harboring STR alleles that differ from their parent, usually by a single repeat within the tandem array. If such sperm or eggs are involved in conception, offspring will be produced exhibiting an STR profile that differs from their true parent.

When a mutation is encountered in a parentage test, it must be incorporated somehow into the overall statistical result. STR mutations are rare events and thus a mismatch between alleged parent and child is more likely evidence of nonparentage than parentage with a mutation. Several methods exist to fairly incorporate an inconsistent result into the overall LR calculation. One is simply to assign the mutation rate as the LR value. Thus, if a locus has a mutation rate of 0.001 and a mismatch is observed, the value 0.001 is simply incorporated as the LR value for that locus. The problem with this approach is that it does conform to the typical method of comparing two hypotheses in an LR. In a more appropriate approach, the two hypotheses compared are: H_0 (the chance that the tested man is the father of the child and a mutation has occurred to produce the mismatched allele inherited by the child (defined by the mutation rate, μ)) versus the alternate hypothesis H_1 (the chance that the tested individual is not the child's parent

(defined by the probability of the locus in question to exclude someone who is falsely accused)). Thus, the LR is calculated as follows:

$$LR = \mu / P_{Ex}$$

As a typical STR locus has a mutation rate of 0.001 and the typical P_{Ex} for an STR locus is 60%, LRs will average about 0.002, which will often mandate that the lab perform additional testing to produce a combined LR of ≥ 100 . Although this approach is closer to the typical method for calculating an LR, it does not consider the transmission of alleles from the parents to the child. Still a third approach for calculation of the LR does consider transmission probabilities.

Consider the following pedigree and STR test results:

Locus	Alleged parent	Child	Known parent
D3S1358	17,19	17,22	16,22
D21S11	32,32.2	32,33.2	30,33.2
FGA	24,28	24,30	29,30
D8S1179	10,12	10,14	14,16
D5S818	10,12	9,13	9,10

For all systems shown in the pedigree, the alleged parent harbors an obligate allele with the exception of the D5S818 locus. At this locus, the obligate allele is 13 and the alleged parent exhibits allele 12 as the closest to the obligate in size. Research has shown that 90–95% of all STR mutations exhibit changes to the tandem array that either add or remove a single repeat. Thus, allele 12 is the most likely candidate precursor allele in the alleged parent that underwent a mutation to become allele 13 in the child. Statistical treatment of this inconsistent result is most appropriately treated as described by Brenner (see <http://www.dna-view.com>) as follows (assume that the frequency of allele 13 is 0.1 and the mutation rate is 0.00116 for the D5S818 locus):

$$\text{Probability of allele 13 from the AF} = [(0.5_{\text{Allele 12 rather than allele 10}}) (\mu_{\text{Mutation rate}}) (0.5_{\text{Increasing in size rather than decreasing in size}}) = (\mu/4) (0.5_{\text{transmission of 9 from Known Parent}}) = H_0$$

H_1 in the LR calculation would reflect the probability of the child from a mating of the known parent and a random, unrelated individual of the same ethnic/racial background. Therefore,

$$H_1 = (0.5_{\text{transmission of 9 from Known Parent}}) (0.1_{\text{transmission of allele 13 from the random parent}}) \\ LR = [(\mu/4) (0.5_{\text{transmission of 9 from Known Parent}})] / [(0.5) (0.1)] = [(0.00116/4) (0.5)] / 0.05 = 0.000145/0.05 = 0.0029.$$

Once the LR has been produced, it is incorporated into the combined LR for all loci in the normal way (i.e., it gets multiplied together with all other loci). Mutations, when they occur, generally force a lab to perform additional testing to produce a combined LR of ≥ 100 .

Future Considerations

Whereas parentage testing has historically occurred in private laboratories and has been performed for civil purposes, the forensic community has increasingly become aware of the utility of family relatedness testing for the investigation of traditional and nontraditional crime. Recently in Los Angeles, a long-standing unsolved series of homicides were finally solved through the use of familial searching of the CODIS database. The perpetrator of the murders was the father of a felon whose profile was in the databank for a nonviolent crime he committed. Many states are now considering legislation that would allow searching of their local databases for relatives of felons as part of the investigation process. It will be important for the lab conducting such searches to have a good understanding of the relevance of LR values produced from potential matches. Likewise, an understanding of family relatedness analysis is critically important for the identification of human remains. Only through a good understanding of the statistical approach to such cases can one have any chance of confidently identifying those victims who, without DNA testing, may never be reunited with their families.

Glossary

Allele frequency The frequency of occurrence of an STR allele in a particular population dataset, used in estimating the significance of a DNA profile match.

F_{ST} A parameter, sometimes known as the co-ancestry coefficient, used in the sub-population model to accommodate for sub-population effects on the significance of a DNA profile match.

Hardy–Weinberg equilibrium A theory to describe the association of alleles at a locus, which assumes independent association of alleles within- and between loci.

Likelihood ratio An estimate made up of the ratio of two conditional probabilities that is used to introduce scientific evidence under Bayes' theorem.

Population database Collections of DNA profile data from individuals who have been grouped according to their ethnicity or bio-geographic ancestry.

Product rule Simple method for estimating the significance of a DNA profile match, which relies on an assumption of Hardy–Weinberg and Linkage equilibria.

STRs Short tandem repeats or microsatellites:

Sub-population model Approach for estimating the significance of a DNA profile match that accommodates for sub-population effects.

Introduction

Forensic DNA profiling using conventional autosomal short tandem repeat (STR) markers typically relies on a comparison between a profile derived from an item of evidence (usually originating from a crime scene) and a profile derived from an individual (who is somehow associated with the matter under investigation). When the profiles under comparison correspond, this indicates that the donor of the known sample may also be the source of the profile derived from the evidence item. The question remains as to what significance, or evidential weight, can be placed on this particular scientific observation and, more importantly, what inference can be drawn from it regarding the involvement of a particular individual in the matter under investigation. Evaluating this question is extremely complex and requires a forensic biologist to apply interpretation skills that are grounded in an array of disciplines including population genetics and statistics. This challenge is exacerbated when the profile itself is complex, such as in the case of mixed-, partial-, or low-template DNA profiles. The inherent difficulty of this aspect of forensic DNA profiling has meant that the attempts to address the issue of significance have been, and remain in some instances, the source of ongoing scientific debate. In addition, this aspect of forensic DNA profiling has been a source of considerable confusion and conjecture within the legal system. Notwithstanding these contextual challenges, accurate assessment of the weight of the DNA evidence is central to its admissibility in courts of law.

A Brief Summary of Approaches to Estimating the Significance of DNA Evidence

Throughout the history of their application, forensic DNA profiling techniques have targeted panels of highly polymorphic (or hypervariable) loci. As such, the profiles produced from these techniques are known to be highly discriminating from individual to individual. Demonstrating this level of

discrimination (essentially the significance of the DNA evidence) typically begins with a survey of the distribution of the alleles and genotypes observed in a population sample. In the early years of forensic DNA profiling, these population samples comprised profiles from 100 to 200 individuals who had been assigned to major population groups, such as Caucasians. The assignment of ethnicity was usually on the basis of self-declaration or appearance. The frequencies of alleles and genotypes observed in these population samples were tested using foundation population genetic tests such as tests for within- and between-locus independence. The results of within- and between-locus independence testing were usually extrapolated to infer concordance or otherwise with Hardy–Weinberg and linkage equilibria, respectively. Departures from Hardy–Weinberg and/or linkage equilibria were rarely observed in the data tested, leading to the view that the association between the alleles and genotypes was independent. This meant that the significance of observing a particular DNA profile match could be estimated by multiplying allele frequencies across the loci profiled using a technique known as the 'product rule,' a method that relies on the assumption of Hardy–Weinberg and linkage equilibria. This approach had long been applied in blood grouping analysis, which in many respects was the forerunner to forensic DNA profiling and had been utilized under very similar circumstances.

The assessment of the significance of DNA evidence using the product rule was controversial and led to the admissibility of this statistical interpretation approach being challenged. In some highly significant legal cases (such as *People v Castro* in the United States and *R v Tran* and *R v Lucas* in Australia), these challenges were accepted as legitimate and the statistical interpretation evidence was excluded. The successful challenges emerged from the basis of population genetics and the view that known human population genetic effects were not adequately addressed through the product rule approach, and therefore, the estimates of the significance of the DNA evidence were flawed and were likely to have an inherent bias in favor of

the prosecution. The level of scientific debate, significant enough to be referred to as the 'DNA wars,' meant that this aspect of the DNA profiling evidence failed the general acceptance admissibility criteria for expert scientific evidence and was excluded. Attempts were made to introduce the scientific data itself (the DNA profile) without an estimate of its significance or evidential weight; however, these were also unsuccessful, as courts felt that without an estimate of significance, jurors would have no sound basis upon which to weigh the strength of the evidence and this would lead to speculation and the potential for the prejudicial effect to outweigh the actual probative value of the evidence. It is important to also bear in mind that the introduction of DNA profiling (or DNA fingerprinting as it was then known) into the criminal justice system had been accompanied by considerable fanfare regarding its revolutionary potential as an evidential tool.

A number of enduring practical effects emerged from this formative period. First, superior courts in a number of countries had ruled that the initial methods for estimating the significance of DNA evidence were inadmissible. This led to significant efforts worldwide to determine a more comprehensive approach to the issue that would address the concerns raised by the broader scientific community. Second, courts had also made it patently clear that forensic DNA evidence would be inadmissible if there was not an accompanying estimate of the strength or significance of the observed DNA results. This accentuated the need to resolve the scientific issues, but it also established the requirement to estimate the statistical strength of forensic DNA evidence in all matters where those results were required to be presented in evidence.

Having now placed the requirement of estimating the significance (or weight) of DNA results as central to its admissibility as evidence, the development of more refined and flexible approaches began to receive considerable attention from the forensic, population genetic, and statistical communities. The issue was also the subject of high-level reviews that sought to establish standards and benchmarks that would stabilize practices within the field and reassure the legal sector. The results of this period of development were the emergence of probabilistic models based on Bayesian principles. In summary, Bayes' theorem allows one to consider what you already know and see how much new evidence changes your assessment of the overall evidence. It relies on considering any given proposition by ascertaining the prior probability (or likelihood) of its occurrence and then measuring the influence of new evidence to arrive at the posterior probability (or likelihood) of the hypothesis. The new evidence is presented as a likelihood ratio (LR), which has a multiplication effect on the prior probability.

The use of Bayes' theorem in the context of forensic evidence interpretation is widely accepted in the international forensic community. The court is interested in one question: 'How much does the scientific evidence alter the probability that the accused is guilty or innocent?' Under these circumstances, the Bayesian approach has distinct advantages over other estimates, if for no other reason than that it forces the scientist to think within the framework of the legal process and answer questions based on the function of the DNA profile as an item of evidential significance.

The basics of the statistical approach commonly applied in this area are as follows:

Consider a suspect has been charged and the court must now assess the probability of his guilt $\Pr(G)$, given the evidence E presented before it, $\Pr(G|E)$?. The scientist can only provide information related to the probability of the evidence $\Pr(E)$. For the purpose of this discussion, E refers to the DNA profiling result requiring assessment – typically, that the defendant's profile G_S matches the crime scene profile G_{CS} .

The significance of the DNA evidence is estimated by evaluating the likelihood of observing the DNA profiling result, given two alternative hypotheses that could explain its occurrence. Typically, these are referred to as the prosecution hypothesis (H_p) and the defense hypothesis (H_d). A generic example of H_p is that the defendant is the source of the crime scene profile. Conversely, a generic example of H_d is that the defendant is not the source of the crime scene profile and that it has originated from an unrelated individual who, by coincidence, shares the same DNA profile as the defendant. These hypotheses are generic but a significant benefit of this approach is that the hypotheses can be altered to better reflect the circumstances of the case. This gives this method great flexibility.

The ratio of these two probabilities is called the likelihood ratio (LR). Mathematically, this is expressed as

$$LR = \frac{\Pr(E|G_{CS}, G_S, H_p)}{\Pr(E|G_{CS}, G_S, H_d)}$$

where E is the DNA profiling result, G_{CS} is the genotype of the crime stain, G_S is the genotype of the defendant, H_p is the prosecution hypothesis, and H_d is the defense hypothesis.

The most widely applied approach that follows the principles outlined above is the subpopulation model of Balding and Nichols. An added advantage of this method is that it incorporates a means to accommodate for population genetic effects occurring as a result of genetic drift. The subpopulation model addresses many of the shortcomings of the product rule that had resulted in the early legal controversies. For example, the subpopulation model expressly rejects the assumption of the Hardy-Weinberg and linkage equilibria (at the population level) and therefore does not rely on an assumption of independence. Employing the subpopulation model requires the evaluation and use of a parameter sometimes known as the coancestry coefficient, or F_{ST} . Estimating F_{ST} requires the collection and analysis of subpopulation data and an appreciation and understanding of the population genetic relationships that exist within and between such groups. Therefore, an inherent advantage of the subpopulation model is the integration of population genetic understanding within the methodology, as it requires a deeper level of awareness and application of population genetics to be a routine aspect of the forensic DNA profiling field. Having a model that accommodates for population genetics embedded within a Bayesian framework that allows for flexible assessment of the relevant hypotheses is a powerful interpretation model that is commonly thought of as a gold standard within the forensic sciences.

To derive the formulae necessary to calculate a DNA likelihood ratio (or match probability, if taking the inverse) under

this framework, Balding and Nichols presented an altered form of Wright's sampling formula. This equation can be used in all common casework circumstances to estimate the probability of observing the next allele in the probative genotype. Mathematically, it is expressed as

$$\frac{(x\theta + (1 - \theta)p_a)}{(1 + (n - 1)\theta)}$$

where x is the number of times the allele under consideration (a) has been observed, n is the total number of alleles observed, p_a is the frequency of allele a in the relevant population, and θ is the coancestry coefficient (or F_{ST}).

From the sampling formula, it is possible to derive likelihood ratio equations for the vast majority of common circumstances encountered in forensic DNA casework, such as single-source stains, mixed profiles, and disputed parentage and kinship investigations. This approach, therefore, forms the basis of the statistical methodology applied in casework.

Practical Application of Estimates of the Significance of DNA Evidence

The evolution of fundamental approaches for evaluating the significance of DNA profiling evidence, such as the subpopulation model, established a basis for evidence interpretation that resolved the major early legal concerns such that admissibility challenges to this evidence began to abate. However, as the forensic DNA profiling field is such a dynamic and rapidly changing one, evidence interpretation methods have also had to undergo constant revision, refinement, and extension, and, after doing so, they have naturally been subjected to further legal scrutiny. In the following sections, the major elements of change and scrutiny are summarized as an indication of the evolution of this already complex area.

Source of Population Data and Understanding the Influence of Population Genetics

When evaluating the DNA profiling results, the generic alternate proposition to explain a match observed between a profile arising from a crime stain and the profile of a sampled individual is that there is another individual, who has not been sampled and would also match the crime stain profile, by chance. This immediately invokes the wider population, which, given our understanding of modern human population genetics, cannot be considered as a homogeneous single population but as a collection of subpopulations that have diverged over time and through factors such as genetic drift have developed distinguishable genetic distributions at the subpopulation level. A natural question arising from these two starting points (that someone in the population may also have a matching profile and that the population is made up of subpopulations) is which subpopulations would be the most relevant to consider, and what would be the implications of selecting the wrong ones? Clearly, this question needs to be considered in relation to the agreed elements of the matter at hand and is not something that can be unilaterally decided in the forensic DNA laboratory. On occasion, such questions

have substantial gravity in a criminal trial and it may be necessary for a forensic scientist to utilize population data from remote collections. Fortunately, through the wide-scale applicability of these issues, a very large amount of population data has been compiled and tested by forensic institutions. Another means to accommodate such issues is through an assessment of a more appropriate value for F_{ST} . This parameter can represent the genetic distance between two populations diverging as a result of genetic drift and as such, increasing the value for F_{ST} in the equations that lead to the significance estimate can compensate for potential disparities between the selected subpopulation and the unknown true offender. In standard reporting protocols, major subpopulations residing in the region are sampled, tested, and applied as a matter of routine in the generation of significance estimates. The estimates also incorporate a value for F_{ST} that is reflective of the population genetic testing of these assembled data sets and other information arising from the understanding of modern human population genetics.

Estimating significance using an approach such as the subpopulation model seeks to accommodate aspects of modern human population genetics that may influence the estimate. This is done in a range of ways. First, the hypotheses chosen to evaluate the significance of the DNA evidence should reflect any relevant considerations that may assist the court or inquiry. For example, if there is reason to consider the proposition that the crime stain was left by a relative of the matching individual, the consideration would drastically alter the value of the final estimate but can be directly evaluated by altering the hypotheses accordingly. Second, the population data relied on in the calculations must have been collected, analyzed, and reported to a standard that is accepted by the forensic community. This process aims to ensure that significant population genetic features of the data are observed and, hence, can be accommodated through thoughtful application of the model. Finally, as a recognition of the fact that our understanding of modern human population genetics at the level relevant for this purpose is still emerging, scientists must ensure that collection, profiling, and analysis occur as an ongoing process, particularly when novel markers are being considered or introduced.

Complex Profiles – Mixtures

The continuing improvement in the sensitivity and robustness of modern DNA profiling techniques has seen their application within the law enforcement context increase and broaden over time. It is possible to recover a probative DNA profile from as few as 50 cells left behind on an evidence item. This is one of the inherent strengths of forensic DNA profiling evidence; however, it is also a characteristic that leads to the observation of mixed DNA profiles, or profiles that have originated from more than one individual. Typically, the observation that the DNA profile is mixed heightens the complexity of the profile interpretation and the estimation of evidential significance. In lay terms, the observation of a mixed DNA profile reduces the overall strength of the evidence against a matching defendant, as the presence of additional DNA increases the number of possible donors who could also have contributed to the stain. Mixed profiles can vary considerably in their complexity and

can therefore be approached in a range of ways. Some approaches seek to simplify the interpretation by making certain assumptions regarding the profile, such as the binary method that often requires an assumption regarding the number of contributors. These methods are sometimes criticized for including subjective, or opinion-based aspects, that taken to their extreme may lead to a nonconservative estimate. Some approaches seek to simplify the interpretation by making no assumptions at all, such as the probability of inclusion or random-man-not-excluded approach. These methods ignore a substantial amount of the scientific data available and as a result can be less accurate. Representative bodies such as the International Society for Forensic Genetics (ISFG) have assisted scientists by producing recommendations on how to approach the interpretation of complex profiles such as mixtures.

Complex Profiles – Partial- or Low-Template DNA Profiles

Partial, or incomplete, DNA profiles also commonly occur in forensic casework. Due to the fact that there is some data absent from the evidential profile, its significance, accordingly, is reduced. In addition, the profile is usually incomplete because of the lack of good-quality DNA in the starting sample, and this may cause stochastic or technical artifacts to also be present in the profile to a greater degree than would be the case in an optimum sample. Partial profiles only complicate the estimate of significance when there is ambiguity over the genotype designation at an individual locus. Standard methods have been extended to accommodate the inclusion of partial loci in the overall estimate.

Profiles derived from low-template samples are also commonplace in forensic science and can often represent the most critical evidence available in a case. For example, in a cold case where evidence from a historic matter is being reexamined, the DNA material would have been subject to substantial degradation and decay. This in turn compromises the ability to retrieve a profile, and often, analysis results in a profile that is partial and/or has stochastic artifacts. Because of the importance of such evidence, techniques have been developed (such as low-copy-number profiling) that further increase the sensitivity of DNA profiling methods and increase the probability of obtaining a usable profile. A side effect of these techniques is that they can exacerbate the likelihood and magnitude of stochastic artifacts, and therefore, their interpretation has required the development of advanced approaches that model the behavior of profile components and accommodate these additional variables in the estimate of significance.

Nonautosomal Markers

Methods for estimating the significance of profiles arising from testing of nonautosomal DNA markers (such as mitochondrial DNA sequences or Y-chromosome STRs) are generally less evolved than those applied to routine autosomal STR profiles. The distinguishing genetic features of nonautosomal profiles prevent the direct application of statistical methods derived for autosomal STRs; however, some similarities apply. While

nonautosomal profiles (or haplotypes) are shared with little to no variation among members of a maternal (in the case of mtDNA) or paternal (in the case of Y-STRs) lineages, it is still necessary to understand the frequency of occurrence of observed haplotypes within relevant subpopulations. Collection and analysis of subpopulation data is in fact more necessary for forensic laboratories utilizing nonautosomal markers, as they are more subject to microdifferentiation at the subpopulation level and this requires understanding and consideration as a component of the estimate of significance. Population data sets of mtDNA or Y-STR haplotypes are queried to determine the number of times the evidential haplotype appears. In most cases, the count of observations itself is presented as the estimate of significance, as application of more advanced probabilistic or Bayesian methods is very complex.

Estimating Significance Following a DNA Database Search

The strength of the DNA evidence resulting from an intelligence database match is often presented without any mention that the match was initially obtained from a database. It is usually not in the defendant's interest to let a jury know that he or she has a sample on the DNA database, as a negative inference may be drawn. The question of whether searching a DNA database for a match affects the significance of the evidence has been discussed extensively and forcefully in the literature. The issue also affects any search among suspects whether they are on a database or not. Unfortunately, there is much confused writing and it has at times proven very difficult for courts to make a reasoned decision in the face of quite divergent scientific views. One school of thought on this issue recommends that an adjustment be made to the estimate of significance if the identification of the defendant followed from a DNA database search. This adjustment suggests reducing the likelihood ratio estimate (or increasing, in the case of a DNA match probability) by a factor equal to the number of people in the database (N). Using a simple example of a DNA database containing the profiles of 100 000 individuals and a profile with a likelihood ratio of 1 000 000, this would result in an adjusted likelihood ratio of 10 being reported to the court. This approach is often referred to as the Np rule, where Np indicates that the random match probability p is multiplied by the size of the database, N . The conservativeness of this recommendation increases as N increases, and the proposal loses logical appeal. For example, if the database were to hold the profiles of the entire world, and there was only one matching individual, it would logically provide an irrefutable association, yet should Np be employed, the discriminating power of the match would be reduced by a factor of seven billion and would be reported as something entirely unconvincing. The alternative school of thought follows Bayesian reasoning to demonstrate that the significance is in fact strengthened by the identification of a matching profile following a DNA database search. This is due to the fact that in conducting such a search, all nonmatching individuals in the database have been excluded, thereby increasing the significance of the evidence against the remaining matched individuals (relative to the circumstance where they had been compared directly without employing a DNA database search).

Glossary

Electrospray ionization (ESI) Ionization technique of biomolecules for mass spectrometry.

Gas chromatography Gas-phase separation method for volatile compounds.

High-performance liquid chromatography (HPLC) Column-based method for separating analytes based on differences in hydrophilic/hydrophobic interactions.

Matrix-assisted laser desorption/ionization

(MALDI) Ionization technique of biomolecules for mass spectrometry.

miniSTR Short tandem repeat loci amplified in short fragment sizes.

Restriction fragment length polymorphism Method of differentiating DNA based on variation at sites recognized by restriction enzymes.

Single-nucleotide polymorphism (SNP) A single base change in a DNA sequence relative to a reference sequence.

Solid-phase extraction Chromatographic technique used to prepare samples for subsequent analysis by removing interfering substances.

Short tandem repeat (STR) Repetitive repeat element used to differentiate DNA.

Variable number of tandem repeats Repetitive repeat element used to differentiate DNA.

Abbreviations

ESI	Electrospray ionization
FTICR	Fourier transform ion cyclotron resonance mass spectrometry
HPLC	High-performance liquid chromatography
ICEMS	Ion-pair reversed-phase liquid chromatography electrospray ionization mass spectrometry
m/z ratio	Mass over charge ratio

MALDI	Matrix-assisted laser desorption/ionization
miniSTR	Short tandem repeat loci amplified in short fragment sizes
MS	Mass spectrometry
SNP	Single-nucleotide polymorphism
STR	Short tandem repeat
TOF	Time of flight

Background

Much of the nuclear variation that has been targeted in forensic genetics is present as fragment length polymorphism. This applies to earlier restriction fragment length polymorphism-based methods, where variable number of tandem repeats alleles were discriminated on flat-bed gels with fragment sizes up to 20 kbp, as well as modern short tandem repeat (STR) loci that are separated under denaturing conditions with sizes up to 500 bp. Discernible size categories are used to number (call) STR alleles relative to sequenced reference alleles. These STR categories are used to calculate allele frequencies that form the basis of statistical evaluations. In the late 1990s, the forensic community witnessed the development of commercially available, larger STR multiplex kits containing between 10 and 15 STR markers and the forensic experts became used to reporting STR profile frequencies beyond 1 in a billion. This development was also triggered by the establishment of national DNA databases that require high discrimination power to confidently identify links between unknown crime scene samples and suspects/convicted persons.

Forensic samples, for example, specimens collected at the scene of a crime, are by nature unpredictable in terms of DNA

quality and quantity. They are often affected by environmental conditions that lead to DNA degradation. As a practical consequence, casework samples often yield partial STR profiles that contain only a reduced number of useful loci, mostly at low-molecular-weight ranges. Partial STR profiles are usually less discriminative and may therefore pose a problem for the practitioner when they fail to provide strong evidence in a case or result in too many adventitious matches in DNA database searches. To compensate for the reduced discrimination power, so-called miniSTR strategies were developed, where amplification primers were moved closer to the repeat region to reduce the amplified fragment size and represent alleles at lower molecular weights. This allows for an increased number of successfully typed loci and, in the case of complementing STR profiles (consensus from different STR multiplex amplifications), helps achieve the required discrimination power. This strategy is, however, restricted by the amount of available DNA. Often DNA quality and quantity are linked in crime scene samples, that is, low DNA amount goes in hand with some degree of degradation, which is why miniSTR analysis does not always resolve the issue. Alternatively, markers that are better suited for the successful analysis of degraded DNA, for example, single-nucleotide

polymorphism (SNP) and insertion/deletion polymorphisms, were also considered but not broadly adopted by the forensic community as standard loci, mainly because of the incompatibility with the existing national DNA databases that seem to lock the selection of forensic STR loci.

Even in the early days of STR typing, so-called variant alleles were observed under nondenaturing electrophoresis conditions. Although their fragment sizes were identical to the 'normal alleles,' they showed slightly different migration patterns. Sequencing studies revealed that they showed variation at single, or few, nucleotide positions, which apparently affected their electrophoretic mobility. While those variants were only rarely considered as separate allele classes – they were usually lumped together with the respective categories of the normal alleles – their observation indicated the presence of additional genetic variation in STRs that remained hidden under denaturing electrophoresis conditions. Could this information be captured by alternative detection methods? And if so, would this additional discriminatory power offset the loss of information caused by partial profiles when degraded DNA is present? These questions raised interest in the application of mass spectrometry (MS)-based methods for the analysis of the forensic STR loci. In contrast to electrophoretic separation where only fragment sizes are estimated, MS-based methods result in molecular masses of the amplified DNA that can be transformed into base composition profiles. This means that not only fragment sizes but also nucleotide variation (substitutions) can be inferred, allowing for discrimination of alleles, which differ in base composition but are of identical length.

In addition to technical questions such as the overall success rates of such approaches, the overall performance of MS, and the potential to automate the process, one would certainly be interested in how much of the additional genetic variation could be detected by MS. Sanger sequencing of forensic STR alleles would theoretically capture all detectable genetic variation present in a sample but is undoubtedly too expensive and too laborious for routine samples (and in many samples not applicable). Next-generation sequencing technologies are still failing to demonstrate the reliability, especially in difficult samples, that would be required in a forensic context. Can MS-based methods compete with the performance of established electrophoresis systems? What are their benefits and limitations? In the following sections, these questions are addressed and the state of the art of MS-based DNA analysis in forensic science discussed.

Mass Spectrometric Methods in Forensic Genetics

Early Work

While the early work of Butler and coworkers clearly demonstrated the applicability of matrix-assisted laser desorption/ionization–time of flight (MALDI–TOF) in the characterization of STRs, there is a notable absence of published reports in which MALDI–Fourier transform ion cyclotron resonance mass spectrometry (FTICR) was employed to characterize nucleic acids associated with forensic markers. The fact that signals from larger oligonucleotide ions derived from polymerase chain reaction (PCR) would appear at significantly higher m/z ratios, where FTICR performance is significantly

degraded, has precluded the implementation of the MALDI–FTICR method to characterize STRs. Additionally, a key consideration for MALDI–FTICR relative to MALDI–TOF is the time scale over which the mass measurement takes place and the inherent delay between ion formation and ion detection. Ions that are internally excited due to the MALDI ionization process have more time to undergo metastable decay on the relatively long time scale of the FTICR measurement (100–1000 ms) compared to the much shorter time scale of a TOF detector (<100 μ s). Even under relatively gentle MALDI conditions, MALDI–FTICR spectra of oligonucleotides greater than about 20 nucleotides in length often exhibit some extent of metastable decay that is typically manifested as loss of one or more neutral purine bases. However, owing to the gentle nature of electrospray ionization (ESI), the ESI–FTICR technique enjoyed early adoption as a method with which to characterize forensic DNA markers derived from both autosomal STRs and mitochondrial DNA (mtDNA).

The first ESI–FTICR analysis of an STR marker (TH01 allele 9.3) was accomplished in the late 1990s on a 4.7 T ESI–FTICR instrument and the same platform was later employed to correctly differentiate between subtypes in the vWA locus that could not be distinguished by traditional gel-based genotyping methods. These studies also demonstrated that the relatively high mass of the PCR amplicons derived from STRs (30–60 kDa) were not particularly amenable to high-performance mass measurements on the FTICR platform. The inherent space charge limit of the trapped ion cell in combination with the added cost and complexities associated with operating the FTICR platform in a 'hands-off' high-throughput modality precluded the broad adoption of ESI–FTICR instrumentation as a viable platform. The commercial availability of benchtop ESI–TOF mass spectrometers, which provided sensitivity and mass accuracies rivaling those of the FTICR platform, ushered in a new era in the mass spectrometric interrogation of DNA forensics markers and laid the foundation for broad implementation in the mainstream forensic community.

ESI–TOF – Current State of the Art

John Bennett Fenn was awarded the Nobel Prize in Chemistry in 2002 for his development of ESI. ESI is particularly useful for the ionization of macromolecules, such as larger DNA fragments, which tend to fragment during ionization with other techniques. The last decade has seen two main approaches to the application of MS to the analysis of forensic markers, both relying on ESI–TOF–MS. The major difference between these two approaches lies in the way in which amplified PCR products are purified and prepared for ESI–MS (as outlined below). This post-PCR purification step is a critical prelude to mass spectrometric analysis as there are a myriad of buffer components (salts, dNTPs, detergents, etc.) that are required for PCR amplification but which are deleterious to the performance of the mass spectrometer as they can interfere with the ionization process and result in uninterpretable mass spectra. The analysis and interpretation of the DNA data is then founded on base composition analysis. Masses derived from a mass spectrum can either be (a) compared to a 'lookup' mass list derived from known sequences or base compositions, or (b) converted directly to base compositions,

which can either be compared to existing base compositions in a database or used to populate a new database. Final base composition assignment for a double-stranded PCR product requires Watson–Crick base pairing between the candidate base compositions for both the forward and reverse single-stranded DNA products (the number of As, Gs, Cs, and Ts of one strand must equal the number of Ts, Cs, Gs, and As of the complementary strand, respectively).

The ICEMS approach

The analytical approach behind the ion-pair reversed-phase liquid chromatography electrospray ionization mass spectrometry (ICE MS) method involves the direct hyphenation of a high-performance liquid chromatography (HPLC) system with the ESI-TOF, which was developed in the early 1990s. The strategy is to load crude PCR products onto the HPLC column, where they are purified and coarsely fractionated and directly injected into the mass spectrometer. Reverse-phase chromatography proved very efficient in purifying and desalting PCR products – an important prerequisite for clean spectra and sensitive detection limits. A great deal of effort has been put into optimizing the chromatographic aspect of this approach to maximize the utility of the ICE MS method. As such, it has been shown that rods filled with octadecylated silica particles, octadecylated polystyrene/divinylbenzene particles, or monolithic polystyrene/divinylbenzene with 10–25 nM butyldimethylamine or cyclohexyldimethylamine as solvents result in improved performance. A key advantage of this approach is that, in addition to amplicon purification, HPLC also provides coarse size fractionation, which facilitates the analysis of complex amplicon mixtures as derived from multiplex PCRs. The Innsbruck group has shown that the analysis of an autosomal STR 14-plex and an mtDNA 23-plex is feasible in one multiplex reaction with typical forensic quality samples.

The Ibis approach

On the Ibis PLEX-ID platform, the mass spectrometric analysis process that follows PCR thermocycling is completely automated. Unlike the HPLC-based method described above, this approach utilizes fully automated anion exchange-based amplicon purification to remove salts, excess dNTPs, polymers, and other constituents of the PCR reaction that can form adducts or add to the chemical noise background in the mass spectra directly from 96-well PCR plates. Two internal mass standards (acidic peptides) that bracket the most informative region of the spectrum (m/z of ~726 to ~1346) are incorporated into the final desalting buffer to aid in subsequent data processing. Using a novel dual electrospray source configuration, this integrated approach allows the fully automated analysis of a PCR reaction every 30 s. Thus, a typical eight-well assay is ‘read’ in only 4 min.

After MS, data processing is automatically triggered by the integrated runtime controller. Data processing employs custom software to (i) remove general background noise, (ii) postcalibrate the raw mass spectrum, using multiple isotope peaks of the internal peptide calibrants, and (iii) ‘deconvolve’ the raw spectrum to produce a simplified spectrum consisting of mass on the X-axis and signal intensity on the Y-axis. The resulting deconvolved mass spectrum is traversed to determine mass peak positions and report final masses in a list that is

imported directly into a database for storage and retrieval during sample analysis. The analysis of laboratory-derived data is encoded as configurable parameters in an automated analysis interface.

Increasing the accuracy by mass tags

To achieve unambiguous base composition determinations for PCR products up to about 130 bp, a mass assignment accuracy of approximately 25 ppm is required. Further, near-neighbor (i.e., SNP-containing) base compositions have forward and reverse strand masses that are similar to each other. For example, products with base compositions of [A46 G20 C32 T39] and [A47 G19 C31 T40] – corresponding to a $G \rightarrow A + T \rightarrow C$ change – have masses that differ by approximately 1 Da for each forward and reverse strand as a $G \rightarrow A$ SNP reduces the mass by 16 Da and a $T \rightarrow C$ SNP increases the mass by 15 Da. With sufficient mass accuracy and precision, which is normally achievable with ESI-TOF-MS analysis, these possibilities can generally be distinguished (albeit not when present simultaneously within the same spectrum). However, because biochemical reactions contain noise and peak shapes are not always perfect in distribution, ambiguity at this level is possible.

With the G_{10} approach (Ibis), PCR is performed with a modified mastermix in which the normal dNTP mix is replaced with one containing normal dATP, dCTP, and dTTP and a modified version of dGTP (G_{10}) containing ten ^{13}C atoms. These ten ‘heavy’ carbons change the mass of each incorporated GTP by 10 Da, and thus, in the case of the $G \rightarrow A$ and $T \rightarrow C$ double SNP offsets the masses of the two strands by ~11 Da, rather than 1 Da, making base composition assignment unambiguous (Figure 1). The use of this isotopically enriched nucleotide analog does not appear to impact PCR efficiency or the incorporation of GTP. Similarly, with the ICE MS approach allele discrimination was improved by replacing dTTP by dUTP in the dNTP mix. Uracil and thymine are both complementary to cytosine but the molecular mass of deoxyuridine is approximately 15 Da less than that of deoxythymidine, which results in improved allele discrimination.

MS-Based Genotypes and Haplotypes to Aid Forensic Analysis

Mass Spectrometric STR Analysis

There has been substantial effort in the forensics community to improve the performance and sensitivity of STR analysis from challenging samples. One strategy, commonly referred to as miniSTRs, applies shortened amplified products by moving amplification primers closer toward the repeat region. Both technologies mentioned above are actually complementary to this methodology and utilize the same approach. The reduction in amplicon sizes increases the resolution obtained during MS analysis. This approach has the following primary advantages: (i) nucleotide polymorphisms are inherently revealed during analysis; (ii) prior information about nucleotide polymorphisms is not required (neither the prior characterization nor the prior localization of an SNP within a PCR product is required for it to be correctly identified); (iii) no

Figure 1 Utility of ^{13}C -enriched dGTP to differentiate analysis SNPs using mass spectrometry. In (a) the PCR products are generated with natural dNTPs; a G $\rightarrow$ A (green) and a T $\rightarrow$ C (red) variant produce amplicons very close in mass to each other (about 1 Da difference) but well-resolved from the base allele (black). (b) When amplified with ^{13}C -enriched dGTP in place of dGTP, a G $\rightarrow$ A (green) and a T $\rightarrow$ C (red) variant from allele 14 produce amplicons separated by nearly 11 Da, which allows unambiguous assignment of each SNP variant. Note that with the use of the ^{13}C -dGTP, there is an unambiguous detection of an SNP from the base allele 14 product (black), and an unambiguous assignment of the base switch involved in the SNP.

allelic ladder is required for any locus analyzed; (iv) no primer labels are required (products are analyzed directly in the mass spectrometer); and (v) alleles of different loci can cross in length, and same-length alleles of one locus can be differentiated if they differ in base composition. This feature deserves explicit attention as it demonstrates that MS-based detection is amenable to DNA analysis with practically all STRs in ‘miniSTR mode,’ whereas locus spacing with CE-based multiplexes allows size reduction for only a portion of markers in a multiplex. Finally, if a novel allele with a length previously not seen is detected, a base composition can be derived directly and a very reasonable hypothesis can be made immediately about the allele structure (although sequencing is still required to ultimately confirm the sequence structure).

Let us take as example the simple STR marker D3S1358 that is widely used in forensic genetics and is part of the core STR panels in the United States (CODIS 13) and Europe (extended European Standard Set of Loci (ESS)). Its repeat region consists of a relatively stable TAGA sequence motif that has been found to range from 8 to 20 units with frequent alleles observed at the higher molecular range (14–19 units). Even in small population studies, remarkable differences in the amount of discernible alleles have been observed between electrophoretic sizing and MS-based analysis. In less than 100 samples from Europe, a total of seven allele categories (alleles 14 through 20) were detected by electrophoresis with the most common alleles 15 and 16 at frequencies exceeding 20%. With MS detection, the number of discernible D3S1358 alleles increased twice as most of the frequent size categories displayed differences in their base composition profile (Figure 2).

Here, T–C exchanges in the repeat motif were observed as a source for the additional variability detected only by MS. Sanger sequencing confirmed the presence of CAGA (instead of TAGA) repeat units at the 3′ end of the repetitive region. This simple example shows that variation in the underlying nucleotide sequence can provide substantial additional discrimination power that is useful in the forensic context. Two immediate questions arise from this observation. What is the

quantitative gain in discrimination power? Is the assumption of allele/sequence identity across various tissues in an individual still valid? There is so far no evidence to doubt the latter statement as somatic mutations, mosaicism, or chimerism have not been reported to act any differently at the level of the nucleotide sequence than they do with respect to the fragment size. This means that we would not expect significant increase in intraindividual differences (between tissues) when moving from fragment size to base composition analysis. However, this issue needs to be verified and demonstrated in the course of systematic validation studies. The first question about the gain in discrimination power is relatively easy to address once the commercial support allows for the establishment of appropriate population data to determine valid allele frequencies. Initial data has already been generated to raise appetite.

An important detail of MS-based STR typing is the fact that data generated with this technology are fully compatible with existing data generated by CE. This means that existing datasets, such as the established national DNA databases, can be used without limitations. Importantly, comparisons with older DNA results are always possible. Any technical development that employs a different set of forensic markers (e.g., SNPs, Indels) would require changes and old data would become irrelevant.

ICEMS approach STR analysis

In 11 out of 21 forensically relevant markers, a significant increase in discrimination power was observed using ICEMS compared to CE already in small sample sizes tested (<100) indicating that nucleotide variation may be more common than anticipated (Table 1).

Two main sources of nucleotide variation were observed: SNPs already established in the HapMap project were found in sequence regions between repeat units and primers such as rs9362477:G > A in SE33 or rs11642858:A > C in D16S539 that led to the identification of new allele variants. In addition, ‘shuffled’ repeat units were observed by ICEMS and later confirmed by direct Sanger sequencing as, for example, in vWA,

[illegible]

Figure 2 Comparison of discernible D3S1358 allele categories with CE and ICEMS based on 98 unrelated European samples. The conventional approach (CE) allows for the discrimination of seven allele classes (14 through 20), whereas the MS-based method (ICE MS) captures additional variant alleles (a total of 14 categories). Detected sequence variants for allele 15 are indicated below the graph.

Table 1 Comparison of discernible allele categories based on electrophoretic sizing (CE) and molecular mass (using the Innsbruck ICMS approach) and the net gain in discrimination power

<i>Locus</i>	N	<i>Number of alleles</i>		<i>PM</i>			<i>h</i>

PM, matching probability; h, heterozygosity.

Source: Pitterl F, Schmidt K, Huber G, et al. (2010) Increasing the discrimination power of forensic STR testing by employing high-performance mass spectrometry, as illustrated in indigenous South African and Central Asian populations. *International Journal of Legal Medicine* 124: 551–558.

Figure 3 Scheme of an autosomal STR 13-plex with the gender-specific marker amelogenin that is coamplified in a single multiplex PCR assay. All markers reside in the low molecular size range (miniSTR), which is only achievable with MS-based detection platforms as conventional CE analysis would not allow for marker separation with current fluorescent dye technology.

where different ratios of the TCTA and TCTG repeat units were determined. This effect is even more pronounced in more complex STRs, such as D2S1338. Here, the varying number of the repeat blocks TGCC, TTCC, and TCCG led to almost twice the number of discernible alleles as compared to pure amplification size variation.

In an effort to combine informative loci in a multiplex reaction, 13 of the autosomal STRs (vWA, D21S11, D3S1358, D16S539, D8S1179, D7S820, D13S317, D5S818, TPOX, CSF1PO, D2S441, D10S1248, and D22S1045) and the gender-specific marker amelogenin were assembled in one PCR multiplex assay (Figure 3) and applied to the analyses of different populations and various types of forensic samples. These experiments indicated that the STR 14-plex was on par with commercially available CE-based STR multiplexes in terms of typing success rate.

Ibis approach STR analysis

Ibis has developed an ESI-TOF-based STR assay that includes the 13 core CODIS STR loci and the sex marker amelogenin. To explore the extent to which SNPs in the STR loci add to the allele pool (and associated resolving power) of the standard CODIS panel, a collection of more than 1000 reference samples was assembled, which had been previously typed by CE performed in the laboratories of collaborators at the FBI, AFDIL, NIST, and UNTHSC. Polymorphisms relative to reference alleles were found in 11 of the 13 loci analyzed. At nine of the 13 loci, SNPs were observed in alleles in which the number of repeats (and thus lengths) of the alleles were identical. These alleles are termed ‘same-length heterozygotes’ as these loci would be typed homozygotic by conventional CE-based methods. In fact, based on the >1000 samples, it appears that the same-length heterozygotic prevalence is approximately 9.3, 9.2, and 8.76% for the loci D3S1358, D13S317, and D5S818, respectively (Figure 4). Four other loci (D8S1179, D21S11, vWA, and D7S820) contained same-length heterozygotic alleles more than 2.5% of the time in this sample set (Table 2).

Mass Spectrometric mtDNA Analysis

Ibis mtDNA control region tiling assay

Ibis developed a 24-primer multiplexed assay that amplifies human mtDNA (mtDNA) hypervariable regions 1 and 2 (HV1 + HV2) by eight triplexed PCR reactions that occupy one column of a 96-well plate (Figures 5 and 6). By anchoring on standardized coordinates, that is, the rCRS, any base composition profile can be directly compared to any other profile produced in this assay or to any mtDNA sequence spanning the same range of amplified coordinates. On the basis of an analysis of 1266 human mtDNA sequences from GenBank, the tiling assay retains the ability to differentiate 94.2% of the entries by one or more base composition differences. The partial loss of information comes from reciprocal SNPs (e.g., C → T + T → C) that are close enough to be contained within a single amplified region. They then produce identical base compositions for that primer pair if they are the only differences between the sequences. The assay also covers a larger coordinate space than the minimal HV1/HV2 sequencing traditionally performed in forensic laboratories (16024–16365, 73–340). For the same 1266 sequences that are distinct in sequence over the tiling coordinates, only 90.2% are discriminated by sequencing of the minimal HV1 and HV2 regions.

A key advantage of MS-based approaches relative to sequencing as applied to heteroplasmic samples is illustrated in Figure 6. Importantly, length heteroplasmy typically manifests as variation in the number of bases residing within a homopolymeric stretch (i.e., C-stretches). In HV1, the region in which this is most often observed, the homopolymeric stretch begins at nucleotide position number 16184. A similar region of length heteroplasmy exists in HV2, encompassing nucleotide positions 303–315 (for more details on length heteroplasmy, see elsewhere in this encyclopedia).

Direct Sanger sequencing has two key limitations when analyzing samples containing length heteroplasmy: (1) sequences that differ by the number of C residues in a homopolymeric stretch produce multiple overlapping sequence patterns that are slightly out of register; this results in an

Figure 4 Illustrations of SNPs within STRs. A ‘same-length heterozygote.’ All ‘allele type 12’ for the D5S818 marker are not equivalent; some contain a G-to-T SNP, which distinguishes them from individuals containing the ‘normal’ allele type 12. The ESI-TOF spectrum illustrates the presence of both a base allele 12 and an allele 12 containing a G → T SNP; using the ^{13}C -enriched dGTP nucleotides results in a net mass difference of 35 Da between the same-length alleles. This sample is genotyped as homozygous 12 by Identifier[®] (ABI).

Table 2 Frequency of observation of polymorphic alleles in 1033 samples typed at 13 CODIS loci using the Ibis high-throughput ESI-TOF mass spectrometry platform. An additional 391 samples were typed at the seven most polymorphic CODIS loci. Note that in six of the loci, SNPs are observed with a prevalence of >23% (confirming most polymorphic markers from the Innsbruck study with much lower sample size, [Table 1](#)) and that in three of the loci, more than 8% of the same-length alleles are ‘same-length heterozygotes’

Locus	Number of alleles with SNPs	Samples tested	Percentage of alleles with one or more SNPs	Number of same-length heterozygous samples	Percentage of samples heterozygous with same-length alleles

uninterpretable sequencing read after the homopolymeric stretch and (2) the contributing species to the homopolymeric profile can sometimes be difficult to be quantified effectively. Both these limitations can be overcome by ESI-MS analysis. First, the mass spectrometer is well-suited to characterize samples containing mixtures because ions at different m/z -ratios are detected independently. Thus, the ability to detect the fragment containing the short homopolymeric stretch is independent of the ability to detect the

fragment containing the long homopolymeric stretch. In MS, there is no analog to being ‘out of register.’ As illustrated in [Figure 6](#), multiple fragments representing multiple genotypes within a given region will generate multiple signals (assuming nonidentical molecular masses of the genotypes). Because fragments of similar length and base composition have similar ionization efficiencies, relative signal intensities can be used to measure the relative amounts of both genotypes in a sample.

Figure 5 Overview of the mtDNA triplex tiling assay. (a) Primer pair groupings by approximate mtDNA spatial locations of grouped primers (left side) and layout of a 12-sample-per-plate assay kit plate. (b) Schematic overview outlining the analysis process for one reaction. Results of eight reactions are automatically tied together to generate a base composition profile. Each entry corresponds to a *start coordinate ... stop coordinate: base composition*. In the example illustrated here, the individual has a base composition of A48 G18 C32 T39 spanning the rCRS coordinates 154–290 (bottom right of figure).

ICEMS mtDNA haplogroup screening

An mtDNA assay for the ICEMS technology was developed by targeting 22 SNPs in the mtDNA coding region and SNP 16519 from the control region (CR), which provides a useful tool for either screening unknown samples or further typing samples that have been analyzed for the CR and require additional analysis for establishing the haplogroup status. The amplified fragments were selected in such a way that they include haplogroup diagnostic markers of mtDNA lineages representative for the West Eurasian phylogeny. Thus, a prescreening of larger population data from this

subcontinental region is also feasible to assess population genetic parameters in a quick and cost-effective manner relative to Sanger sequencing. In total, the approach targeted 627 mitochondrial sites allowing for the detection of additional variation outside the primarily targeted SNPs that can be used for further discrimination. The observed power of discrimination of >98% significantly exceeds that of alternative SNP screening strategies (e.g., single-base extension). It is further observed that the 23-plex was successful in obtaining useful results for even highly degraded samples with maximum amplicon lengths below 131 bp.

Figure 6 Effect of length heteroplasmy upon mtDNA sequencing and the mitochondrial tiling assay. Sequence analysis is severely challenged by multiple templates that differ in length. (a) Forward strand sequence electropherogram of a sequencing reaction developed by direct PCR-product sequencing from in-house saliva sample CS0033 on top. The sequence electropherogram becomes unreadable after the poly-C region because of a mixture of templates of varying length. (b) Deconvolved mass spectrum for primer pair, which amplifies coordinates 16124...16201 encompassing the HV1 poly-C stretch. There are four clearly resolved products that differ by single C residues in the poly-C tract. * ^{13}C -enriched dGTP was used in these reactions, adding ~10 Da to the mass of each G residue.

Conclusions and Future Directions

MS has long been a core component of many forensics laboratories and is the tool of choice for analyzing a wide range of evidence associated with illicit drugs and their metabolites, explosives residue, toxins and adulterants, and other controlled substances. Many of these early applications of forensic MS were catalyzed by the availability of novel separation/purification techniques (gas chromatography, HPLC, SPE, etc.) coupled with highly efficient ionization methods. The studies described above, and many others published elsewhere, illustrate the power of the mass spectrometer as a core analytical platform for DNA-based forensic markers. Clearly, one of the strengths of this platform is that it is in essence a 'universal detector' and has the ability to unwind complexities associated with SNPs, mixtures, and length heteroplasmies, which pose significant challenges to CE- or sequence-based methods. Commercial mass spectrometers have evolved considerably in recent years and benchtop ESI-TOF instruments are now routinely making measurements that would have been challenging for even the most sophisticated (and expensive) mass spectrometers a mere decade ago. The forensics community is only now beginning to appreciate the additional resolving power and breadth the MS platform provides in a forensic

DNA context. Research and development activities focused on improved sample preparation and automation for MS-based analysis of DNA markers are presently underway in a number of labs around the world. It is conceivable that integrated microfluidic approaches will play a prominent role in such endeavors as will a next generation of even smaller and lower cost-integrated robotic platforms, which are directly interfaced with existing laboratory information systems.

Glossary

Adventitious match Result of a database search with ambiguous results due to searching with a partial profile with a low discrimination power (e.g., when the random match probability is equal to or less than the size of the database), where it must be considered that matching database record(s) may not be connected to the crime.

CODIS The Combined DNA Index System is the software system that runs the US National DNA Index System (NDIS), which contains the combined data of all US state DNA databases.

Cold hit A person found in a DNA database search using a crime stain profile who had not been a

suspect in this case based on conventional police investigations.

EDNAP group The European DNA Profiling group was introduced in 1989 by scientists from academic and governmental laboratories to carry out collaborative experiments with the aim of harmonizing forensic DNA profiling methods across Europe.

ESS loci The European Standard Set of STR loci used for database typing.

Familial searching A database search strategy aiming to identify first-degree relatives from unknown perpetrators.

NDNAD The National DNA Database in England and Wales

Introduction

Although the history of national databases storing DNA profiles of criminal offenders and unsolved crime cases is still quite short, it is one of the greatest success stories of modern criminal investigation strategies, at least equal to the introduction of dactyloscopy. In Europe, the first national DNA database was established in England and Wales in 1995. In the USA, the Combined DNA Index System (CODIS) was gradually introduced by the FBI since 1989, and was formally created by the DNA Identification Act of 1994 and launched nationally in 1998. Since then, most of the European countries as well as many countries from all over the world have introduced collections of DNA profiles from criminal cases. It has to be noted, however, that some of these databases only hold data from unsolved crime cases since the storage of offender profiles typically requires specific legislation. As there are significant differences regarding the criminal justice systems, the national databases were created on the background of a specific legal history and culture as reflected by the various national regulations that can now be found. In the countries collecting only crime scene samples, databases typically have been introduced based on existing legislation for samples obtained from routine casework.

However, there are several important issues that need to be decided when database legislation is considered. These include the criteria for adding an offender's DNA profile to the database, the decision to also include suspects (or arrestees, depending on the legislation) prior to the court proceedings, as well as convicted offenders already imprisoned at the time when the database is introduced, the time period for storing a person's profile in the database, and the handling of a person's reference DNA sample (i.e., a blood sample, a buccal swab, and/or a DNA sample extracted from blood or buccal cells) after it has been typed, that is, to retain or to destroy it.

Criteria for the Inclusion of DNA Profiles in National DNA Databases

As there is considerable diversity regarding the legal systems in the European countries, these will be used as examples to point out the relevant issues for the introduction and operation of criminal DNA databases. In most legislations, specific criteria have been defined based on the type or severity of a crime qualifying for storage of DNA profiles obtained from biological stains. Typically, capital and violent crimes as well as all types of sexual offenses are included in most databases. Some countries have adopted a detailed list of criminal offenses for inclusion as defined by the respective penal code (e.g., France and Norway), whereas in others, the length of the time period a convicted offender has to stay in prison is considered. These periods may vary between 1 and 5 years. Furthermore, to store a DNA profile in a database, a formal decision by a judge or investigating magistrate is required. Finally, in a number of countries no specific selection criteria exist (e.g., Austria, England/Wales, and Switzerland; see below).

There are two groups of persons that are considered for a database entry: suspects and/or arrestees in ongoing criminal investigations and convicted offenders. The inclusion of suspects is possible in England, Austria, Croatia, Slovenia, Switzerland, Germany, Finland, Denmark, the Netherlands, and Norway, but the selection criteria for suspects are rather diverse. The most stringent strategy has been implemented in England, Austria, Croatia, Slovenia, and Switzerland, where 'any recordable offense' qualifies the suspect for a database entry. In most countries, however, entry criteria are based on the type of crime (Norway), as well as the length or type of expected conviction, for example, imprisonment for more than a year (Germany, Finland), 1.5 years (Denmark), 4 years (the Netherlands), or even 5 years (Hungary). The inclusion of suspects is not allowed in Belgium, Norway, and Portugal.

The inclusion of suspects at an early stage of the investigation may lead to a situation where the suspect's profile is entered onto the database and generates a match with a DNA profile from another unsolved crime. This 'cold hit' could then lead to a new investigation even if the charges of the initial investigation have already been dropped. Although the database record from a suspect has to be eliminated in most countries if a person has been acquitted, the new investigation related to the cold hit will of course be carried out. It is obvious that this approach will generate more hits when the 'population' of potential offenders grows larger in such a database. This assumption is supported by national DNA database statistics which are exemplified for several countries (see [Table 1](#)). For example, in Belgium, only 47% of the database records are from offenders, and, consequently, only 38% of all database hits are person-stain hits. In countries where more than 70% of the records are from persons, at least 70% of the observed hits are between persons and stains. In England and Wales, about 10% of the population is already in the database. More than 90% of all database records are from persons, and more than 85% are person-stain hits. It has to be considered as well that offender-matched profiles from stain cases are removed, whereas the offender will remain on the database. This results in a much higher 'throughput' rate for stain profiles.

For convicted offenders, the criteria are the same in all countries that also accept suspects. In some of the remaining countries, such as Norway and Belgium, a court decision is required. This is also the case in Germany, where the decision must be justified by a prognosis on the risk of future offenses. In Sweden, a conviction of at least 2 years in prison is required. In the Netherlands, a convicted offender may voluntarily offer his sample for the database, even if the conviction is for a period of less than 4 years. This illustrates that a database entry may also serve to protect the privacy of a convicted offender once he has been released from jail and has decided to obey the law. If such a voluntary sample is included in the DNA database and a new crime scene sample is added without generating a hit, this individual is automatically excluded from being involved in the unsolved case. In France, all cases of sexual assault as well as all serious crimes qualify for a database entry. However, the offender has to donate the sample voluntarily, as he cannot be forced due to laws protecting his physical integrity. Nevertheless, it appears that most offenders agree to have their samples taken, as they are otherwise punished by a fine for denying their sample. Another solution to this dilemma is to collect cigarette butts, hairs, or brushes from those offenders who are resilient to a fine, as the genetic analysis of 'abandoned' samples is not prohibited by the law. Nevertheless, this practice seems to be questionable as the correct establishment of the 'abandoned' sample's identity could be doubtful and prone to error or manipulation.

In England and Wales, database records are still being kept without restriction even for acquitted suspects. However, the legality of this rule was challenged by two individuals who requested their DNA samples and data records to be removed. One of the accused persons, a boy who was only 11 years old when his genetic sample was obtained, was acquitted, and in the second case involving an adult man, no charges were pressed due to a pretrial reconciliation. The request was

eventually denied by the House of Lords, so that the case was brought to the European Court of Human Rights (ECtHR). This court ruled in favor of the request and observed that keeping the samples of acquitted or innocent persons without restriction is a violation of privacy rights as defined in Art. 8 of the European Convention of Human Rights. Subsequently, the British government proposed changes to accommodate the ruling of the ECtHR.

Countries not retaining database records without restrictions have mechanisms in place for their elimination. In countries where suspects are entered into the database, these records have to be eliminated once the charges have been dropped or when the suspect has been acquitted in court. Interestingly, Denmark makes a clear difference between these two scenarios: the record is eliminated immediately when the prosecution has dropped the charges (assuming the police clearly believes that the suspect is innocent), but the record remains on the database for 10 years in case of acquittal (since this may have happened only due to lack of evidence). Convicted offenders will stay forever on the database in the UK, in Austria, Finland, Norway, and Croatia (even for a period after death, as old cases may still be solved when these DNA profiles remain on the database). In the other countries, periods between 10 and 40 years are in place before a record may be eliminated. The decision may also depend on the offender's age or an individual prognosis, as in Germany, or on the severity of the crime (e.g., in Slovenia).

The third aspect to consider is the procedures for collecting and storing the reference samples from suspects and convicted offenders. All countries are now taking buccal swabs as these can be collected without the help of a physician. In a number of countries, bar-coded sampling kits have been developed, which also allow an easy anonymization procedure. Thus, the DNA profiles can be stored separately from the personal information. This is the case in most countries except for Germany where the samples are anonymized only for the typing laboratory, but are stored together with the complete personal information in the police database. A major difference exists regarding the regulations to retain or destroy the reference samples after they have been typed. Samples are kept in the U.K., Austria, Finland, Denmark, Hungary, Slovenia, and Croatia. Thus, it is possible to test the sample again to confirm the data when a match has been called, and before the match report is handed over to the prosecutor. In addition, samples would be available for retyping in case the number of database loci is increased. On the other hand, there are also strong arguments in favor of destroying the samples after the typing results have been obtained. Destruction efficiently prevents any unauthorized use of the samples, and thus ensures the protection of genetic privacy. Furthermore, the destruction of samples does not generate additional long-term expenses for adequate sample storage. In the countries where no reference samples are kept, a fresh sample is usually requested from the suspect when a match report indicates that this person may have been involved in another crime. Thus, the investigation does not rely on the information obtained from the database, but on a fresh sample which can be used as evidence in court, if necessary.

To ensure that the typing results are stored in the database as accurately as possible, most countries have mechanisms in

Table 1 DNA database statistics of selected European countries

Country	Pop. total (million)	Database		Database Population (%)	Persons (%)	Stains (%)	Total hits (thousand)	Person hits (thousand)	Person hits (%)	Including suspects	Last update

^aThe law was changed after some years of operation to include suspects.

place that all reference samples are tested twice. In addition, the technical quality can also be ascertained by requesting that laboratories working for a national DNA database have introduced a quality management system, regularly take part in proficiency testing exercises, and are accredited according to international standards such as ISO 17025. Accreditation will become mandatory in the EU in November 2013 for all forensic DNA laboratories following an EU Council framework decision in 2009.

Genetic Typing Systems

A major effort has been undertaken by the scientific community since 1995 to create a high level of standardization regarding the genetic typing systems. Short tandem repeat (STR) loci are forming the core of all national DNA databases. In Europe, an agreement has been obtained on a common set of STR loci, the European Standard Set (ESS) comprising the seven STR systems: TH01, VWA, FGA, D21S11, D3S1358, D8S1179, and D18S51. Shortly afterwards, the Interpol Standard Set of Loci (ISSOL), which is identical to the ESS loci except for including the Amelogenin locus, has been defined by Interpol. Subsequently, Interpol has also introduced an international platform for a DNA data exchange. In the United States, the FBI Laboratory, which administers the CODIS system, has implemented a common set of 13 STR loci. All seven ESS loci are part of the CODIS marker set, which in addition includes the six loci, CSF1PO, TPOX, D5S818, D7S820, D13S317, and D16S539. In Germany, the STR locus SE33 (humACTBP2) has been included from the beginning of the database operation in 1998 due to its high discrimination power.

In 2005, the European DNA Profiling Group (EDNAP) and the ENFSI DNA Working Group convened to discuss an extension of the ESS loci. It was triggered by a political process with the aim to enable a European data exchange between the EU member states. The Treaty of Prüm was signed in 2005 with the purpose of stepping up cross-border cooperation, particularly in combating terrorism, cross-border crime, and illegal migration. When massive exchanges of DNA profiles are undertaken between national databases following the implementation of the Treaty of Prüm, the seven ESS loci do not have sufficient discrimination power to avoid adventitious matches. These may occur when the power of discrimination of a DNA profile in question is insufficient (e.g., when the random match probability is equal or less than the number of persons in the database), so that it must be considered that the matching database record(s) may not be connected to the crime.

Furthermore, due to the increased sensitivity of STR typing kits, more and more crime stain samples are submitted for analysis either with low amounts of DNA or with compromised DNA quality due to degradation. Typing of such samples typically results in partial profiles with even less power of discrimination. In this situation, robust STR systems with short amplicons are quite useful, as these are more useful for typing degraded DNA samples. A recommendation from the ENFSI and EDNAP groups was adopted to add the five new loci, D1S1656, D2S441, D10S1248, D12S391, and D22S1045, to the ESS. Among these are three short amplicon STR loci (D2, D10, and D22), as well as two loci with a high discrimination

power (D1 and D12). Furthermore, the three STR loci, D2S1338, D16S539, and D19S433, which are routinely typed in many forensic DNA labs, are also being used for the DNA data exchange, increasing the total number of markers to 15 STR loci. Regarding the United States, an FBI CODIS Core Loci Working Group made recommendations in 2011 to expand the STR marker set by selecting loci either from the ESS or from typing kits already used for many years in the forensic community. Selection criteria were based, among others, on discrimination power, lack of association with medical conditions, and a low mutation rate to enable identification of missing persons.

Privacy Rights, Ethical Considerations, and New Directions

The introduction of DNA databases has been accompanied by a lively and sometimes controversial debate about the protection of privacy, as well as the extent to which DNA, both as a source of information as well as from the derived DNA profiles, should be investigated. It has been aptly stated in a review on the ethical context of criminal DNA databases that 'there is an essential tension throughout this discursive field between a wonderment of the ability of DNA to identify the perpetrators of crime and a dread about its capacities to erode civil liberties and human rights.' A major concern is related to the collection of a person's genetic sample containing the entire genomic DNA. Although a DNA sample does not constitute 'personal data,' and is thus not directly covered by data protection provisions, it allows to reconstruct all genetic information from an individual given that the appropriate methods are applied, such as by using the new 'next generation' sequencing technologies allowing to sequence a full human genome in a couple of days. Therefore, even if the current legislation restricts the genetic information to STR typing results, which are stored in a database, there is a strong concern that indefinitely stored DNA samples could be 'abused' without revealing it publicly, or in an unpredictable situation where a radical change of the political system occurs. Therefore, as described above, the majority of countries have decided to discard personal reference samples. In Switzerland, it was initially decided to keep reference samples during an evaluation period of the national DNA database. However, when the final legislation was passed, this provision was removed on the grounds of privacy protection, as well as saving significant costs for secure sample storage.

On the other hand, it has to be noted that a crime stain from an unknown perpetrator does not necessarily constitute a 'private' sample. It has rather been abandoned at a crime scene and thus is not likely to be deemed worthy of protection under any appeal to the privacy of personal information. Consequently, research is underway to extract additional information such as the prediction of biogeographic ancestry, that is, the geographical region where a person has his or her genetic roots. Furthermore, scientific efforts are underway to investigate coding DNA sequences in the hope of obtaining additional clues on the identification of the perpetrator based on externally visible characteristics (EVCs), such as hair, eye and skin color, body height, or facial features, also termed 'Forensic DNA Phenotyping' (FDP). In the Netherlands, DNA legislation was

introduced in 2004 to explicitly allow for this type of genetic investigation. It may be argued that the analysis of coding sequences represents a flagrant violation of privacy rights and will open the floodgates for all other types of investigations on genetic traits in criminal investigations. However, it is quite unlikely that a detailed 'genetic photofit' picture will ever become reality, as EVCs other than pigmentation markers are highly complex genetic traits which might not become easily predictable even if the entire genome is sequenced. Genetic prediction on ECVs from a crime scene has to be based on a likelihood estimate in a range where a considerable margin of error remains. Thus, it will be useful only in cases where the STR-based DNA profile does not generate a hit in the criminal DNA database. It will then only help to narrow down the number of suspects and will have the same or a lower quality as the statement of an eyewitness. Once a particular suspect or a group of suspects has been identified, identity to or exclusion from the crime scene sample will be established using 'conventional' STR typing. Therefore, it must be understood that it does not make any sense to store genetic data on EVCs in criminal DNA databases. These can only be used to provide limited intelligence on an unknown stain donor, and will be discarded once the true perpetrator has been identified by STR analysis.

Another strategy which is considered controversial in some countries, but not in others, is the search for genetic relatedness based on STR profiles in existing criminal DNA databases. This has already been carried out in some states of the USA as well as in the UK, where familial searches helped to identify unknown offenders by linking the crime scene profiles to first-degree relatives of the perpetrator whose DNA profiles were already entered into the DNA database. Whereas this approach is allowed in a number of US states and in England, it is not allowed in many European countries such as Germany and France, as it would be considered not only an intrusion into privacy, but also as an illegal use of genetic information derived from STR profiling. In the courtroom, testimony can be refused by a witness if a relative is accused. However, by carrying out familial searches, the individual from the database suspected to be, for example, the brother of the unknown perpetrator is used as an 'unwilling informant' about his relative. It has also to be considered that the number of STR loci typed for the national databases typically has adequate power for a direct comparison, but may be not large enough to establish sufficiently strong evidence to prove genetic relatedness. Obviously, there are still controversial views about the prospects and limits of DNA evidence as an

intelligence source in criminal investigations when it comes to operate a national DNA database in the framework of the rather diverse criminal justice systems throughout the world.

Glossary

Accuracy In the current document, accuracy is used to define the degree of closeness of the measured value to the actual or true value. An accurate process will show results close to the actual or true value.

Automated liquid handler (ALH) An automated pipetting robot that utilizes preprogrammed scripts to perform laboratory processes.

Calibration curve An ALH may employ a calibration curve to compensate for differences between the physical pumps and liquid handling systems. By measuring the actual volumes delivered by each pipette, a calibration curve can be generated enabling an ALH to attain accurate pipetting over a defined volume range.

Carrier Holder for labware that is designed to fit onto the worktable of an ALH. A carrier may hold several pieces of labware. Usually, different carriers are required to hold different types of labware.

Firmware A small piece of software that is stored directly in the electronic circuits of, for example, an instrument.

Typically, this software is not accessible to the user. In ALHs, firmware may be used to control the individual mechanical parts.

Instrument software Dedicated software used to program scripts for an ALH. Instrument software is usually supplied with the ALH. The software and the possibilities and options as well as terminology vary greatly between vendors.

Labware Items that may be placed on the ALH worktable such as microtiter plates, tubes, tips, troughs, etc., are generally denoted as 'labware.'

Liquid class In the current document, the word liquid class is used. A liquid class is a subpart of a script that

contains a collection of detailed parameters controlling the pipetting operation. A liquid class typically contains instructions to the ALH regarding pipetting speeds, size of air-gaps and, in some instrument softwares, also calibration curves. An ALH may use many different liquid classes in a single script enabling precise liquid handling. In some instrument softwares, liquid classes are denoted as 'liquid types' or 'liquid handling parameters.'

Pipetting technique Pipetting techniques resembles liquid classes, but contain more adjustment options. The term 'pipetting technique' is used in the instrument software from Beckman Coulter in combination with underlying pipetting templates that are used to control the tip movement inside the well/tube for each aspiration–dispense operation.

Precision In the current document, precision is used to define the degree of reproducibility or repeatability. A precise process will show the same results with unchanged conditions. A precise process does not infer that the process is accurate.

Script In the current document, the word script is used. A script is a series of software instructions that directs the ALH to perform the desired functions such as aspirating–dispensing liquids, recording of barcodes, transfer of labware, and so on. In some instrument softwares, scripts are denoted 'methods' or 'routines.'

Worktable In the current document, the word 'worktable' is used. The worktable is a graphical representation of the area used by the ALH to process samples. In some instrument softwares, worktable is denoted as 'instrument deck' or 'deck layout.'

Introduction

Automation of manual pipetting devices commenced in the 1970s with the introduction of the digital diluter by the Hamilton Company. The first automated liquid handler (ALH) was presented in 1983. The term laboratory automation or simply automation usually refers to the use of these ALHs. Presently, ALHs are commercially available from many vendors. Some are sold as stand-alone (open platform) systems, while others are designed and constructed according to detailed specifications set forth by the customer. Many options exist for integration of equipment such as centrifuges, scales, heater/shakers, magnetic purification units, conveyer belts, sealers, PCR cyclers, and more. Hence, this combination allows complete laboratory processes to be performed without manual intervention. Applying automated systems in the laboratory is not per definition the most economical solution. It depends on the capacity of the automated system and the sample throughput of the laboratory.

However, implementation of automated solutions has several other important advantages for a forensic laboratory. ALHs run or execute scripts containing detailed instructions that enable liquid-dependent pipetting to compensate for variations in the physical characteristics of the liquid such as viscosity, volatility, and so on, similar to manual pipetting by a laboratory technician. An ALH will perform the same set of pipetting operations during each run, reducing intra- and interoperator-induced variations. ALHs are incapable of performing actions that they are not programmed to perform, and the risk of sample misplacement or unintended pipetting is close to zero, given that the ALH is designed and programmed with this in mind and samples and reagents are loaded correctly. Finally, automation of more complex laboratory processes will often reduce process time and increase process capacity. In this chapter, the choice of liquid handler, validation and implementation of liquid handlers in a forensic and accredited environment, and operation and maintenance of liquid handlers are discussed.

What is a Laboratory Information Management System

A laboratory information management system (LIMS) is a computer system that manages sample-related information, results of analyses, manual and automated laboratory workflows, user profiles, user access, and so on. Some LIMSs also include options for managing case report information. The level of sample management and options for addition of laboratory result in the LIMS differ between system and vendor. Many different ‘commercial off-the-shelf (COTS) systems’ exist. However, forensic laboratories may choose to either modify a COTS system to fit specific local requirements or develop their own LIMS. Usage of a LIMS requires that the information entered is trustworthy. Hence, much effort must be put into ensuring the validity of sample data and results upon registration in the LIMS, and whenever possible, electronic data and automated result entry should be applied. If manual data entry is the only option, the data should be entered independently twice or at least approved by a second operator.

General Benefits of Laboratory Automation and LIMS

Implementation of laboratory automation and LIMS in forensic environments is about prioritizing and managing resources. Implementation and validation of laboratory automation systems and LIMS are neither simple nor cheap. Furthermore, dedicated staff should be assigned to perform routine maintenance and support of both automated instruments as well as the LIMS to ensure that the systems are up to date and deliver the expected performance. Automation reduces the amount of manual processing of samples and a LIMS eliminates manual sample tracking. Combined, laboratory automation and LIMS reduce the sample-to-sample processing variation and, when used correctly, reduce the risk of sample misplacement. Implementation of laboratory automation and LIMS may enable a laboratory to better handle the daily fluctuation and reduce the throughput time. Most importantly, implementation of laboratory automation with LIMS integration enables laboratories to increase the throughput far beyond what is attainable using manual processing. Furthermore, implementation of additional identical ALHs is relatively simple and provides the laboratory with a scalable solution, should throughput requirement increase.

Selection of an ALH

Multiple ALHs are now commercially available. In general, they are all capable of performing the task their name suggests, namely automated handling of liquids. The general differences between the liquid handlers are mainly caused by (1) the way the ALHs aspirate and dispense the liquids, (2) the software used to program and control the instrument, and (3) the degree of integration of additional equipment with the instrument and the software.

General Differences Between ALHs

Most ALHs function by positive displacement of either air or a ‘system liquid.’ ALHs using air displacement function, in

principle, as conventional hand-held pipettes. ALHs relying on system liquid generally utilize distilled water as system liquid. As the compressibility of water is less dependent upon changes in temperature and pressure than air, some regard liquid-driven ALHs to be better in situations involving large temperature/pressure fluctuations. Some ALHs are capable of monitoring the processing of the pipetting, for example, by following the liquid by conductive tips or comparing the pressure difference encountered during pipetting with a predefined liquid-specific reference. This reduces the effect of bubbles and clots and improves overall confidence to the results.

The instrument software used to generate the scripts varies greatly between vendors. Some programs enable scripts to be programmed by dragging function boxes into a vertical or horizontal row resembling the principle of Lego. Others rely on line-to-line programming. The level of control of the function of ALHs also varies greatly between different types of software. Details such as direct control of the tip movement inside the well/tube during pipetting may be possible in one type of software while being impossible in another. Functionalities such as locking of scripts to prevent undesired modifications, user control, etc., also vary between the various instrument software solutions. For larger ALHs with integrated equipment, the instrument software may assist the programmer by scheduling the resources of the ALH enabling faster completion of the script. The instrument software may also include tools for locking or validating a script once it has been completed and sufficiently tested. In general, the different vendors have different tools for safeguarding a validated method. Some are more efficient than others.

ALHs may be divided into three main groups based on their size and flexibility. Small liquid handlers may be closed systems with dedicated functionalities such as small DNA extractors or small ALHs with limited flexibility and integration options. Medium-sized ALHs are typically more open and flexible, enabling a higher degree of customization and integration of various components and equipment. Large ALHs typically contain multiple components such as handling arms, sealers, capper/decappers, centrifuges, cameras, and so on, and are capable of performing complex processes without manual intervention, enabling large ALHs to function as a production line. A rule of thumb is, the more complex the solution, the more complex and extensive the validation. Hence, the choice of solution should fit a laboratory’s needs – a big, complex, and expensive ALH is not always better than a simple solution.

Automation of Laboratory Processes

Crucial to the selection of the optimal ALH for a specific laboratory process is a careful evaluation of the laboratory process that the ALH is planned to perform. The evaluation is best prepared by listing each individual operation of the process, that is, all transfers of sample/reagents, movements of samples, etc. The evaluation should result in a list of requirements specifying in detail the demands. The list of requirements should specify the requirements to accuracy and precision of the individual liquid transfer steps in the process. The requirements should also state requirements for which type of tips to be used. As disposable conductive filter-tips are expensive, ALHs

equipped with reusable washable tips may be advantageous should filter-tips not be required. The list of requirements should also include relevant evaluation requirements of all potentially integrated equipment such as magnetic units, heater/shakers, etc. The requirements should be as stringent as the intended processes require them to be. If a LIMS is to be used in connection with the instrument, requirements to the input/output file formats should also be specified. On the basis of the list of requirements, the best ALH for that laboratory process may be identified. For laboratories with limited automation experience, vendors with available local/regional support should be prioritized.

Before the implementation and validation of an ALH, a backup solution should be considered. As with all technical equipment, ALHs may malfunction due to a collision or a failure on one of the components. The more equipment that has been integrated on the ALH, the greater the risk of one of the components to malfunction or break down rendering the entire automated system out of service. A situation where a group of samples are required to be processed on a single instrument – a key instrument – should be avoided. One solution, following validation of one ALH is to purchase and validate a second identical ALH. The sample flow through the laboratory may then be directed to either of the two liquid handlers. In any case, key instruments should not be used at more than around 70% capacity to reduce the sample backlog from growing too fast in case of the ALH being out of service. Laboratories operating with a key instrument should have an alternative sample processing solution as backup.

An important consideration regarding integration of various components into one ALH is a cost–benefit evaluation. Typically, integration of equipment from the same vendor is straightforward and the instrument software is prepared for the equipment. Integration of third-party equipment must be considered more thoroughly. Generally, it is cumbersome and time-consuming and the integration must be weighed against manual intervention for completion of the process on stand-alone equipment. Depending upon technical competences of the laboratory staff, integration of third-party equipment may not be economically justifiable. Hence, a solution requiring manual intervention during the laboratory process may be the best, economically feasible solution.

LIMS Support/Integration

LIMS integration requires exchange of information either by a shared database or transfer of files. The level of available LIMS support may have a significant impact on the selection of the optimal ALH. Laboratories with no or very limited LIMS support may benefit from choosing simple stand-alone ALHs. The simplest ALH may be controlled by a simple control panel rather than a PC. This reduces the cost of the instrument and the validation as well as the requirements to the operators in terms of computer skills. LIMS integration may not be possible with these instruments. The flexibility and the integration options of the smaller ALHs may be significantly lower than those of the medium-sized ALHs or simply not existing. However, being simple with limited flexibility ensures that fewer options must be tested and validated enabling faster validation and implementation.

Medium-sized ALHs generally offer greater flexibility, and options for integration as well as communication with a LIMS. The pipetting arm may be automatic adjustable (span) enabling the ALHs to efficiently transfer samples from tubes to plates or vice versa. The deck size allows for multiple tubes in carriers as well as microtiter plates and hence allows more complex processes. This enables the medium-sized ALHs to be used for more complex laboratory processes utilizing various labware. The instrument software controlling most medium-sized ALHs enables processing of samples according to information contained in simple input files, for example, generated by a LIMS. Medium-sized ALHs may be used without LIMS integration, but they generally benefit from LIMS integration.

Integration of multiple components or equipment may enable larger ALHs to perform several usually separate laboratory processes without requirements for manual intervention. Such ALHs may be referred to as production lines. These systems may have a sample processing capacity hardly attainable using manual processing. Such systems seem of little relevance unless they are supported and integrated with an efficient LIMS guiding the flow of samples.

Barcodes

Barcodes are available in many forms and as commercially available fonts. The information contained in a barcode is dependent upon the type of barcode used. Some barcodes are one-dimensional and do not hold as much information per unit-area when compared to two-dimensional barcodes. While some one-dimensional barcodes also contain the humanly readable text held in the barcode, two-dimensional barcodes are not humanly readable. Many commercially available tubes and microtiter plates can be prebarcoded with a unique number. Usage of prebarcoded tubes generally requires LIMS integration to link the sample identification with the number of the barcoded tube.

Custom barcodes may be manually applied to tubes and microtiter plates during sample registration or job creation. Labeling of sample tubes and plates with barcodes enables ALHs equipped with barcode scanners to control the position of the samples as well as the orientation of the microtiter plates, record the labels on the tubes and plates and report the processed samples and plates to either a LIMS or a report file. Sample tracking by barcodes is most efficiently performed with LIMS integration. The LIMS may be programmed to update the status of the processed samples with batch number, instrument details, etc. upon completion of a job. This requires that the ALH automatically generates an output file containing this information and transfers the file to the LIMS.

Recent interest in radiofrequency identification technologies (RFID) for tagging and tracking evidence may indicate a new direction for LIMS, chains of custody, and warehousing.

Tubes Versus Microtiter Plates

One important decision before selecting an ALH is whether the laboratory processes require samples to be processed in tubes or in microtiter plates. Processing of samples in tubes increases the risk of sample misplacement if not a proper control

method such as barcodes is efficiently used. However, having samples in individual tubes eases processing of reruns.

Processing of samples in microtiter plates reduces the risk of sample misplacement as well as the number of manual number controls per sample. However, reruns of individual samples in microtiter plates are difficult to perform manually and, in general, require an ALH capable of processing a few pre-selected samples (cherry picking). Carriers for both conventional flip-cap tubes such as the conventional Eppendorf tubes and support bases for microtiter plates are commercially available from several vendors.

Validation of Automated Systems and Laboratory Processes

When an ALH is installed, the vendor should perform an 'instrument qualification' test to verify that all the components are present and functioning according to the user requirement or 'design qualification' set forth by the laboratory. The result of the instrument qualification test should be documented and stored by the laboratory. The laboratory may perform an additional 'operational qualification' test to ensure that the ALH functions according to the intended use, before commencing actual validation of the ALH.

What Is Validation

According to the ISO 17025 standard, validation is defined as "... the confirmation by examination and the provision of objective evidence that the particular requirements for a specific intended use are fulfilled." In other words, validation is the process that demonstrates that a process or method is robust, reliable, and reproducible in the hands of the technical staff in the laboratory.

Validation Process

Implementation and validation of ALHs are most efficiently handled using project management tools. Hence, a project group containing dedicated staff should be formed and the project prioritized by the laboratory management. In practice, this ensures faster and more robust implementation and validation of the ALHs. Following validation of the ALH, the project group should assist the receiving laboratory in training and maintaining the ALH.

Before commencing a validation project, the instrument should be tested to ensure that it meets the demands of the intended process. This testing may be referred to as 'instrument qualification' or 'user acceptance test.' Instrument qualification should provide documented evidence that the intended process may be satisfactorily executed on the specific instrument.

Script Design

For computerized systems such as ALHs and LIMS, the definition of validation may be interpreted in such a way that every possible relevant outcome of the script should be tested. This should be taken into account prior to script development for ALHs. Most scripts will at some point in time require changes

Figure 1 Script design. A script designed to treat from one to four plates may be differently programmed structurally. (a) The script is designed to treat either one plate, two plates, three plates, or four plates based on initial user input. (b) The script is designed to start with plate one and continue through plate two, three, and four until all the plates are treated.

that invalidate the initial validation, hence requiring a re-validation before use. If the process flow in the script is designed as in [Figure 1\(a\)](#), validation and revalidation may be extremely costly and time-consuming. However, by using a process flow as depicted in [Figure 1\(b\)](#), validation and revalidation may be a simple operation, requiring only a single execution of the full script and treatment of four plates. In comparison, the script design in [Figure 1\(a\)](#) would require four runs and a total of ten plates.

Following completion of the initial script version, testing should commence before the actual validation experiments. Replacing reagents with water may be used to verify the script performance as well as LIMS integration in terms of acceptance of input from the LIMS and generation of output acceptable to the LIMS. Differentially colored water may be used to verify sample positioning, reagent additions, etc. For validation, a representative number of samples should be tested to ensure that the system delivers reproducible and reliable results. Defining the required number of samples to be used for this is a trade-off. For some processes, a magic number of 50 is often mentioned. With automated processes potentially working in 96, 384 or even 1536 well microtiter plates, this number seems irrelevant. Running 50 samples may seem too little as this is less than one full plate. Running 50 plates will be too expensive in terms of reagents and time-consuming in terms of data analysis. Hence, determining the relevant number of samples to be tested very much depends upon process-specific conditions. The relevant number of samples and other relevant acceptance test criteria should be defined before the validation process by or in agreement with the laboratory management.

Worktable Layout

Using small modifications to the carriers may prevent the operators from orienting or placing the labware incorrectly. For microtiter plates barcoded on one of the sides, the position, orientation, and identity may be controlled and verified by ALH in combination with the LIMS initially in the script before sample processing. For simple ALHs, the positioning may be assisted by the use of different types of microtiter plates

Figure 2 Microtiter plate orientation. A stainless steel spike located in the lower right corner indicated with a red arrow is used to secure the orientation of a microtiter plate on a Beckman Coulter Biomek 3000 robot. The microtiter plate (Eppendorf twin.tec) lacks all corners but the corner closest to position A1. Correct orientation of the microtiter plate is with well A1 in the upper left corner (a) Correct orientation of the microtiter plate. Position A1 is in the upper left corner. (b) Incorrect orientation of the microtiter plate. Position A1 is in the lower right corner. The spike prevents the plate from being placed incorrectly in the support base.

for source and destinations. Plate orientation may be controlled by addition of elements on the worktable such as small stainless steel spikes located at positions where the microtiter plate has defined characteristics (Figure 2).

Volume Verification

Verification of the volumes delivered by the ALH must be performed. Verification of the volumes dispensed by the ALH should be performed using the same or alternative representative volumes and aspirate–dispense cycles as used in the script(s) to be validated. The aspirate–dispense cycles should employ the same liquid classes as well as other pipetting parameters such as pipetting techniques and/or pipetting templates as the actual script(s). It may be most practical to write dedicated volume verification scripts for each ALH. Volume verification may be used to optimize liquid classes or pipetting techniques to meet the demands posed to pipetting accuracy and precision.

Volume verification may be performed using gravimetry, fluorescence, absorbance, or radioisotopic techniques. Radioisotopic techniques are impractical due to the biohazard and the many restrictions on radioactive materials and will not be discussed.

Fluorescence

Volume verification by fluorescence requires that a liquid mixed with a fluorescent dye is aspirated and dispensed using the same volumes and aspirate–dispense cycles as the actual script(s). The destination plate should be compatible with a fluorescent-based reader and have flat bottom-wells to ensure maximal signal recording. Repetition of the aspirate–dispense cycles will provide the statistics required. Following dispensing, and signal recording, the signal strengths recorded in each well can be used to calculate the dispensed volume of liquid. This requires use of a standard curve spanning the volumes used. This standard curve should be contained in the same plate as the volume measurement to eliminate potential plate effects. A large number of fluorescent dyes are commercially available. However, fluorescent dyes are known to photo bleach reducing the measurement precision. Furthermore, the signal strength of fluorescent dyes is strongly influenced by factors such as pH and ionic strength.

Absorbance

Volume verification using absorbance is, in principle, similar to fluorescence-based techniques. Unlike fluorescence, volume

verification by absorbance takes advantage of the physical properties of some dyes to block the passage of light. Dyes used for absorbance are hence not as sensitive to photodecomposition, influence by the pH, and ionic strengths as fluorescent dyes. Furthermore, plate readers capable of recording fluorescence are significantly more complex and expensive than the simpler absorbance plate readers. Using a standard curve and repeated aspirate–dispense cycles of the volume to be tested, an accurate measurement of the pipetting operation may be obtained.

Gravimetric

The gravimetric technique is based on the same principle as conventional weighing of dispensed liquid by a manual plunger-operated pipette. The technique generally requires a high precision scale to be integrated in the ALH. The gravimetric techniques may be tailored to use the same liquids such as anticoagulated blood, blood from deceased, other body fluids, PCR master mix, volatile reagents, etc., enabling accurate testing of the complete aspirate–dispense cycles as well as the liquid parameters. Knowledge of the density of the liquid is required to calculate the dispensed volume. However, integration of the scale may be time-consuming and limited to the possibility offered in the ALH software. Furthermore, the scale may not easily be moved between ALHs and hence the same solution may not be employed on all ALHs in the laboratory. The gravimetric method may be performed without integrating the scale on the ALH. The process would then be performed by manual weighing of tubes/plates before and after each pipetting operation. This procedure is laborious and time-consuming.

For handling of samples in plates, the gravimetric techniques only provide the weight of the entire plate unless the change in weight is recorded following each individual dispense operation. Hence, the result obtained is an average over the entire plate and individual variations within the pipetting may be difficult to record. It may be possible to integrate the scale in the ALH script enabling recording of individual pipetting operation, but this may be limited by the options available within the software.

Input/Output Files

Most medium-sized or larger ALHs have the option of accepting and generating files. Typically, these files are simple text files with a predefined structure and formatting. If the ALH is

integrated with a LIMS, this may ensure that only samples in queue for the process being performed on the ALH are treated. The ALH may also be directed to use an input file to ensure correct positioning of the samples on the worktable before sample treatment by controlling the barcodes on the sample tubes or plates, preventing sample misplacement. The output file from the ALH may be generated following sample treatment. The LIMS may be programmed to accept this file and update the status of the treated samples and optionally include any obtained results. Validation of the usage of these files should focus on ensuring that acceptable files are generated, that they contain the expected information, that they are located as expected, and that they are capable of inducing the required response in the ALH/LIMS.

Validation Strategy

Validation of the automated process on the ALH should be as thorough as necessary. One frequent problem is not having an agreement with the laboratory management regarding the extent of the validation and what results are acceptable. Hence, before commencing the actual validation experiments, an agreement between the laboratory management and the project manager should be made. The agreement should depict the extent of experiments including type and number of samples as well as test acceptance criteria. The test acceptance criteria should be the laboratory management minimum requirements to the system.

Modular testing

Validation of individual components of an integrated system or individual subscripts within a larger script or specific LIMS interactions may be performed on a modular basis. Examples of modular testing include volume verification of the pipettes on an ALH, reagent distribution from a trough to preselected wells in a microtiter plate, generation of output file, or import and processing of a file. Relevant results from the modular testing could be included in the final validation report as confirmation of the function of the individual components and interactions. However, a validation should never be based solely on multiple modular tests of the involved components.

Holistic testing

In holistic testing, the entire system is viewed as a black box and the final output is recorded and evaluated. The individual substeps during processing of the samples are ignored. Holistic testing should be performed only when the individual components or substeps have been sufficiently tested using modular testing. The final validation of an automated system should imply holistic testing to demonstrate that the system functions as a whole and the interaction between substeps is as expected.

Contamination testing

The worktables of ALHs are often limited in space. During execution of the script, tips filled with samples or reagents may pass over open wells or tubes. If the liquid classes are not properly optimized, dripping may occur. Cross-contamination may be identified by running a series of known samples, for example, in a checkerboard format

in which the sample in every other well/tube is replaced with water.

Accuracy and precision

To ensure that the system is robust and yields accurate and precise results, the same set of known samples should be processed using the same set of downstream instruments several times over several days. Comparison of the results and potential log or report files should provide evidence to support that the system provides accurate and precise results. Using samples with known concentrations of either DNA or inhibitors, or other effectors provides information on the accuracy of the results.

Sensitivity and stochastic studies

Identification of the lower operation range of the system is best found using dilution series of known samples. Samples with known concentrations may be purchased for this purpose. The dilution series should extend beyond the expected upper and lower detection threshold of the system. Repeating the sensitivity run enables detection of potential stochastic effects from exponential enzymatic reactions such as the PCR. The operating concentration thresholds should be defined on the basis of both the sensitivity of the system and the absence of stochastic effects.

Operation and Maintenance of Automated Instruments in Forensic Environments

Operation of automated instruments in forensic and accredited environments infers that the systems must be safeguarded from modifications or adjustments that will invalidate the validation. Though this may seem obvious, it may easily be overlooked due to lack of detailed knowledge of the instrument software and related equipment. Different vendors have developed different solutions for safeguarding their systems. Some solutions appear more practical than others. In addition, the instrument must be tested with predefined intervals in order to verify that the performance remains within the specifications.

Shared Components of Validated Scripts

The instrument software used to control the ALH or a COTS LIMS often provides various levels of user rights. The typical operator has rights only to execute validated scripts or perform simple routine steps in a LIMS. Hence, the danger rarely lies in the daily users, but in the persons with super user rights. Only details regarding ALH are discussed in the following section.

Instrument software may utilize several shared components. Examples of this include liquid classes, pipetting techniques, labware information, worktable layout, etc. As the components are shared, it infers that they are shared across different scripts. Hence, if a liquid class is modified in one script, the changes are transferred to all other scripts using that liquid class. As the liquid class contains the pipetting parameters, and for some software also calibration curves, changes in a liquid class should at the very least be accompanied by volume verification of all relevant volumes. In some instrument software, this also includes validated and locked

scripts. Others may have various ways of safeguarding the validated scripts.

Development of new scripts for testing on an instrument also used for routine work should be performed with utmost care with shared components. A modification of, for example, a liquid class in a script under development that is also used in a script used for routine work may result in modification of the way a liquid is aspirated or dispensed. To prevent this, liquid classes and other customizable components should be script specific, for example, by using the script name as a part of the component name.

Instrument Software and Script Updates

As with other software solutions, new versions of the ALH software are occasionally released. Often, the new version adds extended functionalities in addition to fixing reported bugs. Implementation of new software versions should be performed only when required and accompanied by revalidation of the system and scripts.

Change strategy

Before making changes to instruments and software used for routine or accredited use, a change strategy should be established. A change strategy is an evaluation of the planned changes and a risk assessment of the consequences. Following completion of the change strategy, it should be documented and included in the revalidation.

Software updates

The simplest solution for updating the ALH software while allowing for continuous use of the ALH during revalidation is to install the updated software on a new PC and only use this new PC during validation. The PCs should be properly labeled to ensure that samples are not processed with the unvalidated software update. Some ALHs (Tecan, etc.) may require firmware (section 'Firmware upgrade') upgrading in combination with the software upgrade. Switching between the new and old PC should here also be accompanied by a firmware upgrade or downgrade, respectively.

Script updates

Substitution of one type of labware, for example, plate type, for another may require modifications in the scripts. Calibration of the instrument by modifying the liquid classes by the addition of a calibration curve is another way of modifying a script. Integration of additional equipment on the ALH or integration with the LIMS system may also require the script to be updated.

All script updates should be performed in a structured and planned manner ensuring that only the desired changes are made. The change strategy may also be used here. Revalidation of the script should focus on verifying the consequences of the introduced changes. The number of samples or runs required to document this should depend on both the system and the changes.

Firmware upgrade

The firmware of various components of the ALH may be updated by a service engineer during regular preventative maintenance (PM) of the ALH. Rarely, the laboratory is

informed about this unless the laboratory has made arrangement with the service companies. Updating the firmware of the parts of the instruments that control, for example, liquid handling or temperature, potentially alters the function of the ALH and hence, in principle, invalidates the instrument. To prevent the service engineer from performing the update, a procedure or signed agreement for how this should be performed should be available prior to PMs. Firmware updates should be handled like other instrument updates. The effect of the update should be estimated and suitable experiments that can verify that the instrument performs as well or better following the update should be conducted and evaluated before the instrument is used for routine work again.

Maintenance

ALHs must be checked at regular intervals ensuring the performance continues to meet the demands posed to all parts of the ALH. These demands may be specified in the user requirement or a modification of these requirements. Most vendors offer a service agreement with planned and detailed PM inspections. The service agreement may include a defined maximum company response time in case of instrument breakdown as well as different levels of PMs. The laboratory should choose the service agreement containing the required balance of service and support options for each instrument. During a PM, a trained and certified service engineer inspects and verifies that the instrument performs according to a check list. Worn parts such as drive belts, system liquid tubings, and so on, are replaced with new ones. The specific details of the PM are contained in the service agreement. Following a PM, the service engineer should complete a service document specifying the performance of the instrument. This document should be filed as documentation for the performance status of the instrument. Following a PM, the laboratory should perform a performance check of the instrument with known samples to ensure that the instrument performs according to the user requirements before any samples are processed on the instrument. The pipetting performance should be verified ensuring that the expected volume is also the delivered volume. It is crucial that the aspiration-dispense cycles used in the actual validated scripts are controlled with the relevant volumes. If it is not possible to have this performed during a PM by the service engineer, the laboratory should implement their own volume verification strategy. For integrated equipment such as magnetic separation units, heater/shakers, etc., tests should be defined and designed ensuring that the equipment performs as inspected under those conditions as required in the validated scripts.

Summary

Laboratory automation including ALHs and LIMS is undergoing a major development. The current options for automation, integration, transfer of data as well as data management seem endless and nothing seems impossible to automate and integrate in the production flow. Even simple laboratory equipment may provide an option for data transfer to a LIMS. For a forensic environment, the challenges are to ensure that the

quality of the automated processes is comparable to or better than that of manual processing. Preferably, implementation of laboratory automation should not only increase sample throughput, the quality of the obtained results of the laboratory processes should also be increased. Furthermore, the automated solutions should have a quality so that they can be validated and accredited according to ISO 17025 or a similar internationally recognized standard. To ensure that the quality of the data management of laboratory results meets the quality of the automated laboratory processes, an efficient LIMS is required. The LIMS should be capable of ensuring efficient processing of the samples through all laboratory steps as well as of storing not only the obtained results but also sufficient information of each process step, enabling traceability and chain of custody.

Ancestry Informative Markers

C Phillips, University of Santiago de Compostela, Galicia, Spain

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Admixture The effects of the combination of two or more populations leading to patterns of mixed variation that originally may have been common to only one contributing population.

Allele The alternative variants that create a polymorphism. Binary polymorphisms such as single-nucleotide polymorphisms (SNPs) show two alleles.

Autosomes/autosomal Chromosomes that do not control gender.

Genotype A combination of two alleles sited on the maternal and paternal chromosomes (or singly in uniparentally inherited markers).

Polymorphism The presence of variant forms of a gene, nucleotide sequence, or repeated genome segment where the minor variant is found at a minimum 1% frequency.

Uniparental Variation carried on the Y chromosome or the mitochondria that is inherited from one parent.

The First Forensic Ancestry Informative Markers: Early Use of Ancestry Informative Protein Polymorphisms Demonstrated Their Value for Investigations

As early as the 1960s, the Duffy blood group, based on serological detection of red cell antigen alleles FY*A and FY*B, was routinely used as a polymorphic marker in forensic biology laboratories. The strong association of African ancestry with the Duffy-null/negative phenotype (written Fy[a-b-] as both alleles are unexpressed due to an independent promotor variant) provided additional data from the same test that suggested a likely African ancestry component for Fy[a-b-] bloodstain donors. By the late 1970s, three additional red cell enzyme polymorphisms were used to specifically detect population diagnostic variation, comprising the hemoglobin S variant plus enzyme systems peptidase A and carbonic anhydrase. The key characteristic of these systems was an allele frequency distribution specific to Africans, that is, absent from other continental regions, albeit at relatively low 8–12% frequencies in African populations. This meant informative genotypes occurred in 22%, 21%, and 15% of Africans, respectively, yet the three tests collectively offered indicative data in 46% of cases, as shown in [Figure 1\(a\)](#). Peptidase A protein, expressed in semen as well as in erythrocytes, allowed this system to successfully track the movements of a serial rapist active in South London and helped investigators link the crimes. This case and others indicated to scientists and investigators alike that despite a low frequency of ancestry informative genotypes, some markers could often provide robust indicators of ancestry. The Duffy system, where over 99% of genotypes are African informative, further highlights the forensic value of ancestry inference when variation is specific to a particular population group. Of course, this represents an overly simplistic view of ancestry inference for several reasons: very few polymorphisms show such clear divides between population groups; most groups are considerably less differentiated (divergent) than African–non-African population comparisons suggest; genetic differentiation between groups rapidly breaks down with the population admixture that typifies urban and postcolonial populations; and few, if any, markers are completely diagnostic of any one group – notably Duffy-negative genotypes are absent from Khoisan Africans ([Figure 1\(b\)](#)). Now that forensic analysis is firmly in the DNA era, perhaps the most

important lesson from early application of simple polymorphisms to infer that ancestry is their proven ability to give valuable investigative leads in certain circumstances, for example, when an eyewitness is absent or, of more relevance for today's forensic analyses, when no DNA database entry exists.

Y-Chromosome and Mitochondrial DNA Variation

The prompt introduction of mitochondrial DNA (mt-DNA) sequencing followed by characterization and use of Y-chromosome variation (NRY) alongside STR typing led to early recognition of the ancestry informative value of these two haploid markers. Each represents nonrecombining genome portions inherited uniparentally: unchanged from mother to offspring (mt-DNA) or father to son. Defining an individual's mt-DNA and NRY lineages therefore suggests shared ancestry with others carrying identical lineages and can be compared to global population surveys of lineage distributions that have become highly differentiated since migrants first left Africa. Furthermore, it may benefit forensic investigations to infer the parental ancestries of a DNA donor – particularly when each lineage is different.

Two problems arise when attempting to match an individual's uniparental lineages to particular populations. First, the mt-DNA and NRY genome portions are only a fraction of the total and may be atypical of the sum of population histories contributing to an individual's whole ancestry. The chance of finding atypical lineages increases in populations that have migrated or admixed in recent history, exemplified by Parsis: showing characteristic Iranian NRY lineages contrasting with mt-DNA lineages more typical of Gujarat. As almost everyone has some ancestry from different regions, ancestry analysis based on two markers alone risks erroneous inference from concentrating on a relatively small proportion of the genome. Second, the basis of the population specificity of particular lineages is dependent on the extent of population sampling preceding the analysis. Surveying haploid marker distributions necessitates typing all relevant variant sites at once and as one unit; therefore, much greater numbers are needed to count each haplotype and inevitably substantial areas of a region lack surveys. Furthermore,

Figure 1 (a) Allele and genotype frequency distributions in three population groups of four previously used forensic ancestry informative polymorphisms. *Informative genotypes denote African-indicative heterozygotes and homozygotes combined. Pie chart summaries are HapMap population data. (b) Population allele frequency data of Duffy AIM-SNP rs2814778 indicating atypical frequencies in Khoisan Africans and effect of AFR–EUR admixture in African Americans. CSA = Central-South Asians (Gujarati Indians in Houston), EAS = E-ASN.

certain lineages can become dominant and are shared across quite extensive geographic areas – notably the Y-chromosome C*(x3C3c) sublineage is shared by 0.5% of all males worldwide, as it is such a dominant feature of central Asian NRY variability.

Despite these limitations, mt-DNA and NRY typing offers strong differentiation of the ancestry of two portions of a donor's DNA; so, a prudent measure for forensic laboratories tempted to draw ancestry inferences from haploid data is to review this variation alongside autosomal ancestry informative markers (AIMs) to provide multiple points of comparison and reduce the risk of biased ancestry inferences.

Points of Reference: Defining Populations or Ancestries, Ancestry Informativeness Metrics, Types of Autosomal AIMs, and Population Diversity Reference Panels

Defining human populations or ancestries can be a highly sensitive issue that excites strong feelings, particularly as labeling or categorizing people is a crude measure that ignores many of the most important aspects of each individual's distinctive cultural heritage. A widespread concern for ethicists is the danger that inference of ancestry in a forensic context will lead to targeting of particular communities with the burden of proof passing to members of that community when DNA profiling for elimination purposes focuses on voluntary programs screening reduced suspect groups. Many specialists advocate purely geographic terms to define an ancestry or population of origin, avoiding descriptions concentrating on visible characteristics such as 'Black' and 'White.' Other common descriptions such as 'Caucasian' or 'Hispanic,' though widely understood, lack geographic precision. Overall, population labels without a geographic definition often hide a large amount of heterogeneity within the group. This article uses five continental-scale descriptions (herein abbreviated): sub-Saharan African (AFR), Eurasian (EUR) – comprising European, Middle Eastern-North African, and Central-South Asian (Indian subcontinent) population groups – East Asian (E-ASN), native American (AME), and Oceanian (OCE). These descriptions follow a broadly continental distribution of population diversity delimited by geographic barriers to large-scale population movements and repeatedly shown to match well to distributions of genetic variation. Any

focus on population diversity can lose sight of a simple, universally recorded characteristic of human genetic variability: the differences between individuals within the same population describe ~85% of total variation, with differences between populations accounting for just 15%. Despite this very small proportion, there is clearly genetic variation that can be selected and built into forensically viable DNA tests.

Assessing strategies to select forensic AIMs leads to the question of how to first measure the ancestry informativeness of any given locus based on particular population comparisons. Traditionally, the population substructure metric F_{st} , analyzing levels of heterozygosity, is used to measure population differentiation; however, F_{st} works less efficiently assessing a marker's individual informativeness. F_{st} does not adequately reflect underlying diversity beyond pairwise population comparisons and extends poorly from binary polymorphisms such as Single Nucleotide Polymorphisms (SNPs) to multiple-allele loci such as short tandem repeats (STRs). The very simple δ allele frequency differential, useful as a quick assessment of binary AIMs (δ : allele frequency in population 1 minus that in population 2), provides surprisingly good F_{st} approximations: $F_{st} \approx \delta^2$ or $F_{st} \approx \delta/(2 - \delta)$. However, the need to properly assess any marker's ancestry informativeness has brought consensus behind using the more appropriate metric of divergence or In . The common nomenclature to denote three group comparisons of AFR–EUR–E-ASN is In_3 , extended to include AME, In_4 . Although reviewing ancestry informativeness metrics may seem a detail, the major constraint in forensic analyses is that the input DNA available to successfully genotype marker sets; therefore, it is essential to choose the most informative loci for combination into small-scale, manageable PCR multiplexes. The most informative markers for a particular population comparison will additionally best measure levels of admixture between those populations. Figure 2 shows the relationship between the divergence metrics δ , F_{st} , and In comparing two population groups.

The study developing the In Divergence metric went on to compare average informativeness of different types of autosomal markers (i.e., not those of X, Y, or mt-DNA). Unsurprisingly, multiple-allele STRs had much higher In values than binary loci (mainly SNPs but including indels: bi-allelic insertion/deletion polymorphisms). This underlines the importance of average allele numbers per STR (those studied averaged 12.4). However, despite the great majority of binary

Figure 2 The relationship between F_{st} and I_n population divergence metrics comparing Africans and Europeans for increasing values of the δ allele frequency differential. Examples of AIM-SNP composite markers of the 34-plex forensic multiplex are aligned underneath their δ values.

loci being considerably less informative than all 377 STRs typed, about 1% of SNPs gave the highest I_n values of any marker. So, what are the implications for building viable forensic AIM sets? First, a large catalog of human SNPs offers the best chance to find the loci most differentiated between populations and therefore the best markers available. Second, though fewer indels have been described than SNPs, they offer similar possibilities and bring their own valuable characteristics to forensic analysis. Third, forensic STR data generated for identification purposes are likely to provide some ancestry information too. Since forensic STRs generally show low population divergence, these data add value to dedicated ancestry marker sets rather than offering a viable alternative by themselves.

DNA sample panels of globally distributed populations are the most important resource for selecting AIMs but remain limited in scope and patchy in their continental focus. The most widely used panel and most comprehensive population distribution is provided by the Human Genome Diversity Panel—Centre d'Etude du Polymorphisme Humain (HGDP-CEPH) comprising 949 samples in 52 populations: 7 AFR, 8 EUR, 17 E-ASN, 5 AME, and 2 OCE (plus four Middle East and nine Central-South Asian). Additionally, the community resource HapMap and 1000 Genomes projects provide extensive SNP catalogs, typing continental and admixed populations, each likely to be continually extended in global

coverage. To date, both projects have not characterized parental (unadmixed) AME or OCE populations. The easiest way to access and discover AIMs from the above population resources is to screen online allele frequency data. Although individual project websites provide marker-by-marker access, a collective approach is better, whether comparing sets of SNPs, chromosome spans, or population divergent genes (e.g., pigmentation genes). Fortunately, this is possible using the *SPSmart* suite detailed in the online resources section, with the opportunity to directly download reference genotypes into all the population statistical analyses suggested in section '[Statistical Analysis of AIM Genotype Data.](#)'

Autosomal AIM-SNPs

Autosomal SNPs have been the principal focus for building initial standalone forensic AIM sets. Despite random sets of STRs usually being more informative, searching for the most differentiated SNPs will identify the best AIMs of all, while SNPs bring considerable benefits to forensic analysis. First, there are much more extensive catalogs of SNPs than other markers, all allowing scrutiny of major group (AFR–EUR–E-ASN) differentiations. Recent genome-scale sequencing extends this catalog to SNPs with ~1% minor allele frequencies,

though notably these methods are less efficient in detecting copy number variation: STRs and indels. SNPs also bring benefits from typing much shorter amplified fragments than STRs, so there is a higher quantity of intact DNA for the PCR stage. Binary polymorphisms are easier to fit into larger multiplexes because short fragment amplification is more efficient and the allele detection stage can more easily accommodate pairs of alleles compared to larger ranges such as the 25–30 alleles of complex forensic STRs. Lastly, a range of platforms are available for genotyping SNPs and their scope per reaction has now reached the million marker level providing the possibility of a much more detailed analysis of human population divergence. The choice of high-throughput genotyping approaches available is regularly listed as a favorable factor for adapting SNP analysis to forensic identification. However, this ignores a critical shortcoming of these techniques that restricts their potential application to forensics – the amount of input DNA required generally far exceeds the 1–20 ng typically extracted from forensic material. As ancestry analysis would normally be an adjunct to identification with STRs, there are further limits to how many reactions could be realistically added to an average DNA case. Furthermore, police investigators carry raised expectations that contact traces with subnanogram levels of DNA are well within the sensitivity limits of forensic laboratories. For this reason, two relatively small-scale multiplex AIM-SNP sets are highlighted using simple *SNaPshot* primer extension assays, typing 34 SNPs in a single test and 24 SNPs in two tests developed by Lao et al.

A third study reported a much larger 176 AIM-SNP set developed by Halder, thereby offering higher overall informativeness. However, Halder's set was designed around discontinued genotyping chemistry: the chip-based Beckman-Coulter *SNPstream* system. Although *SNPstream* showed good forensic sensitivity and could type up to 48 SNPs per reaction, it was hampered by requiring proprietary consumables/instruments as well as the need to group identical SNP substitutions and strands together into discrete PCRs (e.g., G/A, C/T, G/T, and C/A). Thus, the minimum number of reactions (not publicly reported) is likely 6–8, comprising 16G/T-A/C SNPs, 16G/C, and 147C/T-A/G. In comparison, *SNaPshot* uses established forensic DNA instrumentation and is relatively simple to adapt to different SNP sets, while showing by far the best forensic sensitivity of any current SNP typing system. The major limitation of *SNaPshot* is frequent signal peak imbalances caused by differences in the reaction dynamics of the four dye-linked terminators, making mixed-source DNA detection difficult to achieve. This is particularly important for AIM-SNP analysis where a forensic mixture comprising donors with different ancestries could easily mimic a single-source profile from an individual with admixed ancestry. Reviews of forensic AIM-SNP candidates should also take account of published marker lists, despite lacking multiplex designs or being based on singleplex Taqman genotyping. Two such SNP sets have been proposed for forensic use: 128 AIM-SNPs collated by Kosoy and 47 AIM-SNPs mainly overlapping the 24 of Lao above selected by Kersbergen.

Table 1 lists the most informative component AIM-SNPs of the above five sets ranked by *In3* and showing *In4*, estimated using 1000 Genomes and HGDP-CEPH genotypes, respectively (Lao/Kersbergen *In4* omitted due to missing HGDP-CEPH SNPs). Two interesting features emerge from

178 SNPs cumulative In		30.967	31.487

Individual marker *In3* and *In4* divergences are listed comparing African–European–East Asian or African–European–East Asian–American genotypes obtained from 1000 Genomes data (SPSsmart: <http://spsmart.cesga.es/engines.php?dataSet=engines>). The cumulative values under each list represent the final divergences that can be expected with complete SNP profiles from each test. Bold rs-number SNP identifiers denote just two common loci among the alternative tests.

these comparisons: marker commonality, that is, top AIM-SNPs chosen by multiple studies are confined to just two loci: rs2814778 (Duffy) or rs16891982 and most of the top 24–34 SNP components have broadly comparable *In* ancestry informativeness. These observations may partly reflect the selection strategies used. The 34-plex and Halder AIM-SNPs were accumulated over several years of searching for highly differentiated allele frequencies in online databases, whereas Lao/Kersbergen and Kosoy screened whole-genome scan (WGS) data of 10 000 and 300 000 SNPs, respectively. The comparability of the best markers in each set indicates that different AIM selection approaches can each provide informative sets; so, there are more than enough ancestry informative SNPs available to select markers that can multiplex well and provide sufficiently wide genomic distribution. The noticeably small number of extremely differentiated AIM-SNPs, for example, *In3* 0.75, not only indicates how difficult it is to find such SNPs but also reflects their absence from WGS marker sets due to a lack of association power, since these loci have almost no variability within any one population group. Lastly, there are contrasting cumulative *In4* values between 34-plex and the two large-scale SNP sets, indicating different approaches in marker selection, with the 34-plex selected for three group differentiations but now supplemented with a 28-plex stand-alone AIM-SNP multiplex dedicated to differentiating AME populations. This follows the 2008 publication of HGDP–CEPH genotypes for over 650 000 SNPs – enabling selection of many more markers close to fixation (i.e., allele frequencies at or near 1.0 exclusively in one or more groups) in both AME and OCE groups. In summary, the prospects are good for further development of AIM-SNP multiplexes with forensic viability and scale.

Indels

Short-allele indels (1–5 nucleotide insertions, infrequently extending to >25) have recently generated interest as a simple but robust forensic marker type since they combine the best characteristics of binary polymorphisms – short amplicon

lengths and mutational stability – with the best characteristics of STRs, direct typing with dye-linked PCR primers to provide balanced peak height ratios. Although the most divergent ancestry informative indels are less differentiated than the best SNPs, they exceed many STRs. This makes indels highly suitable loci for building multiplexes based on direct PCR-to-CE systems considerably more reliable than *SNaPshot* SNP typing. Two forensic AIM-indel panels have been developed: a single reaction 46-plex of Pereira and three 16-plex reactions of Santos. In addition to the obvious benefit of a single reaction compared to three, the AIM-indels chosen by Pereira were designed to differentiate four groups with a high overall *In4* value, while those of Santos show weak E-ASN differentiation.

STRs

It might be expected that multiallele STRs will show greater population divergence than SNPs or indels. However, STR alleles are highly unstable compared to binary loci, so new STR repeat alleles are constantly being created, while slippage size constraints lead to ‘allelic resonance’: high rates of diminution mutation in long alleles and high rates of addition in short alleles. Therefore, individuals with different ancestries can be identical by state, while those from the same population can show more STR differentiation than their shared ancestry would suggest. Furthermore, unless STR alleles are rare they will not usually be lost after population isolation, although very reduced population numbers typical of founder groups can lead to a rapid rise in frequency of rare alleles by sampling effects followed by population expansion. One such example is the population-specific nine repeat allele of D9S1120 – found at very low frequency in East Siberia but reaching an average 0.3 frequency in native Americans. It is noteworthy that this is the only example of a common population-specific STR allele, highlighting that different populations tend to share the majority of their STR variability, and divergence is characterized by relatively small frequency differences in these shared alleles. For this reason, attempts to infer ancestry from forensic STR profile data tend to show assignment error rates too high for reliable inferences from STR data alone. This is not to say that STRs are completely uninformative for ancestry, as forensic STR population divergence is high enough to make combining

them with other AIMs an ideal way to maximize the informativeness value of the casework genetic data as a whole.

Statistical Analysis of AIM Genotype Data

Of paramount importance in the statistical analysis of AIM data is proper consideration of the confidence limits – the levels of uncertainty associated with the ancestry inferences made. Four factors influence the degree of uncertainty of ancestry analyses: (1) the distribution of diversity among populations, (2) the AIMs used, (3) population reference data used, and (4) the statistical methods used. Genetic diversity could be more readily gauged if global population sampling was more complete than it currently is; however, more importantly, population admixture resulting from urbanization, migration, slavery, and colonization creates far more complex distributions than the divergence patterns suggested by sample panels targeting unadmixed ancestral populations. The same complexities apply to populations on continental margins where geographic barriers are weak. Therefore, statistical tests most sensitive to admixture are the most appropriate for forensic DNA typing analyzing samples dominated by urban demographics. Furthermore, developers of forensic AIM-SNP panels have made efforts to assess the accuracy of ancestry inferences obtained from their markers. Accuracy here means how often an erroneous inference is made of standard reference samples but could include how well an individual admixture is gauged. Maximizing accuracy involves: including as many AIMs close to fixation as possible, maximizing multiplex sizes, and balancing predictive power across each pairwise population comparison (E-ASN vs. EUR and particularly E-ASN vs. AME are especially difficult to raise). There is also some consensus on using statistical tests based on Bayesian methods: either with direct likelihood ratios between alternative populations of origin or as the analytical basis of the ubiquitous model-based clustering algorithm *Structure*. Unfortunately, detection and assessment of individual admixture is the biggest statistical problem confronting forensic ancestry inference using small-scale AIM sets.

Figure 3 outlines the Bayesian likelihood system that can be used to infer ancestry by equating likelihood of population membership with allele frequencies in each population, using example AIM-SNP rs12075. AIMs can be combined into Bayesian analyses either as single profiles which are compared

Figure 3 Illustration of the principle of Bayesian likelihood calculations shown for AIM-SNP rs12075. This statistical approach equates probability of population membership to allele frequency distributions in that population; for example, the A allele is very uncommon in AFR, so the two highest likelihood ratios for the AA genotype are for E-ASN and EUR.

to user-input reference data for the same loci (training sets) using *Snipper* (see Relevant Websites) or in joint analyses of unknowns and reference samples together in *Structure*. Alternatively, principal component analysis provides a visual representation of the divergence distances between reference population clusters and inspection of an unknown sample's position can allow an inference of how each position/cluster is related. *Structure* can be used to provide a system for estimating the ratio of individual-level coefficients of coancestry as indicators of admixture, but this approach does not have the same capacity as analyses of population-level admixture. Kidd, analyzing the Kosoy AIM-single-nucleotide polymorphism (SNP) set, provides a good review of the drawbacks of *Structure* analyses which include stochastic effects between

runs, population sample size effects, incomplete geographic coverage, and AIM set deficiencies (e.g., Kosoy AIMs lack E-ASN differentiation). Unfortunately individual admixture is common, but, more problematically, *Structure* can give patterns from intermediate populations on continental margins that mimic admixture. For example, a North African analyzed in a five-group comparison that does not include North African reference samples could suggest mainly European ancestry with an African component suggesting an individual with admixed parentage rather than ancestry from a region intermediate to the continental reference populations used. Limited reference populations force *Structure* to fit the unknown into the available patterns of genetic divergence. Figure 4 outlines exactly the same circumstances described above using a partial

Figure 4 Structure analysis of a forensic DNA sample in an identification case. Structure identifies groups or clusters of samples based on distinctive allele frequency distributions. An unknown sample is compared to the reference allele frequencies obtained here from the HGDP-CEPH panel for 26 AIM-SNPs and 46 AIM-indels. Multiple analyses identify the optimum number of clusters: K – in this case five, where the probability value plateaus. The triangle plot positions the sample (light blue) in relation to CEPH samples where proximity to the vertex corresponds to the highest probability of membership (shown as overall values for each population in the table). Examination of the membership proportions of the sample can be interpreted as indications of coancestry in the individual or admixed parentage. This suggests mainly European ancestry with a minor African admixture component. In fact, the sample ancestry was consequently shown to be North African – a population not used as a reference in this analysis. Furthermore, North Africans are too closely related to Europeans to be adequately differentiated using the 72 AIMs typed in the analysis.

34-plex SNP profile and the 46-plex indel panel described in section 'Indels.' Such limitations emphasize the importance of drawing together as much genetic information as possible and dedicating resources to collating the widest possible population reference data. Lastly, rising computer power allows multiple *Structure* runs to be easily made to establish population metric confidence limits by reaching stabilized standard deviation estimates – this generally takes 25–30 runs to achieve.

Developments on the Horizon: Expanding Human SNP Catalogs, Combining Marker Types, Further Differentiation of Continental Population Groups, and X-Chromosome Markers

At the time of writing, forensic ancestry inference is gathering pace and raising interest with investigators often guided by unreliable eyewitness accounts. Therefore, it is appropriate to highlight improvements in genetic ancestry analysis already underway or soon to be introduced.

First, the 1000 Genomes project has provided an extended human SNP catalog able to collate rare variation (close to 1% minor allele frequencies) in a growing range of populations. As whole-genome sequencing becomes more routine, forensic DNA analysis can make use of this expanding data resource. It is worth noting that triallelic SNPs, often showing high ancestry informativeness (two are included in 34-plex), are not detected by next-generation sequencing methods – a lost opportunity to expand knowledge of their genomic distribution and population variability.

Forensic ancestry inference greatly benefits from the use of all available genetic data and appropriately all three statistical

systems outlined above accept multiple and binary allele data together. STR data considerably boost the informativeness of even the best binary AIMs and, since all autosomal markers are independent, their combination provides increased reliability to the statistical inferences of ancestry. Figure 5 shows that component I_n3 values for four different marker sets are remarkably similar. Since each marker type brings particular advantages to analysis of the same DNA, their combination to build a fuller picture of a donor's ancestry overcomes shortcomings of any one multiplex. To allow combination of different markers in *Snipper*, users can now upload allele frequency-based training sets as well as genotypes and their likelihoods then combined to provide an overall value.

In addition to small SNP multiplexes, the possibility of using large-scale WGS SNP arrays promises greatly increased population resolution, with prospects to go to a greater depth of differentiation than continental-scale population comparisons. Two 2008 studies showed that populations within Europe could be differentiated across reduced geographic scales ranging from 300 to 1000 km. A more realistic target for improved resolution in the immediate future could be the differentiation of European, Middle East–North African, and South Asian subpopulations of Eurasia. While Europeans and South Asians can be differentiated with small-scale additional AIM-SNP multiplexes, North African–Middle East populations are too closely related to Europeans for reliable differentiation. Therefore, subcontinental differentiation awaits developments to increase multiplex scale and detection limits in forensic SNP typing.

Lastly, X-chromosome variation has been largely overlooked for ancestry analysis. The $\frac{3}{4}$ chromosome population size and reduced recombination have created strong patterns of population divergence in a larger proportion of markers than

Figure 5 Ranked divergence values, I_n3 and I_n4 , of component loci in forensic multiplexes: AIM-indel 46-plex, AIM-SNP 34-plex, 20 core forensic identification STRs, and X chromosome AIM-SNPs 17-plex under development in the author's laboratory. The informativeness order of the 20 component STRs is individually listed. Plots show the autosomal SNPs, X SNPs, and indels combined into ancestry informative multiplexes which are highly comparable – with marginally improved AME differentiation from certain AIM-indel components. Additionally, STRs routinely used for forensic identification have higher I_n4 ancestry informativeness than almost half of the other set's components.

equivalent autosomes. Furthermore, X AIMS in males can provide additional indicators of the ancestry of the maternal lineage alongside mt-DNA analysis.

Acknowledgments

The author would like to thank Carla Santos, Antonio Salas of the Forensic Genetics Unit, USC, and Rui Pereira of IPATIMUP, Oporto, for helpful and enlightening discussions.

Introduction

In every disaster or conflict, the need to recover and identify the deceased is a matter of urgency, foremost on behalf of the psychological needs of relatives of those missing; the right to know the fate of one's missing relatives is a fundamental right and should be respected and enacted – this principle holds regardless of the circumstances that have led to the death. Alongside humanitarian needs, disaster victim identification (DVI) also addresses legal concerns regarding everything from civil suits concerning liability in an aviation, train, or ferry disaster, the need to provide death certificates for purposes of inheritance and remarriage, through to the prosecution of perpetrators of war crimes.

The scope of DVI operations has evolved significantly since the mid-1990s, when most instances centered on transport accidents involving up to a few hundred victims. Advances have been driven in part technically by developments, particularly in DNA analysis, that have increased the circumstances in which identification of human remains is possible. Politically, the response to several events of international importance in the late twentieth and early twenty-first centuries, such as conflicts in the Balkans 1991–99, the World Trade Center attack 2001, and the pan-Asian Tsunamis 2004, focused a large amount of resource to the identification of the victims. This led to logistical and technical advances in DVI and also to higher expectations for forensic science to be used for human identification following disasters and conflicts, even when there are thousands of victims.

Disaster Classification

A disaster can be defined as an unexpected event causing death or injury to many people. Traditional considerations for activating a DVI response related to 'mass disasters', where external assistance was required following a catastrophic event that overwhelmed the resources of an affected community and rendered it unable to respond adequately acting alone. There are many different types of disaster that can necessitate DVI including traffic accidents, natural disasters, technical/industrial accidents, terrorist attacks, and events that occur during conflict, both within and between countries.

In addition to the type of disaster, an important aspect when considering DVI is whether it is open or closed. Closed disasters, such as aircraft crashes, are those in which the identities of the victims are known through crew and passenger

manifests (although these may not be entirely accurate in all cases); in such instances, the task of the DVI team is largely to match the identity of the remains to individuals known to be missing. In many of these cases, access to relevant antemortem (AM) information necessary for matching is also facilitated by the relative ease of locating kin, medical and dental records, and DNA samples. Open disasters are those in which the identity and even the number of the victims are unknown. Establishing who was indeed a victim can be quite complicated even in a thoroughly modern society where it may take several days or weeks, even years to resolve in a situation of limited fatalities; in the case of a natural disaster involving multiple countries or locations within a country and thousands to tens of thousands of victims of multiple nationalities, it can take years to resolve. For victims of conflict, where the number and identity of victims are unknown, individuals disappeared over several years (or decades), the location of graves has been obscured, AM records are scant or lacking in their entirety and political will and monetary resources are slim, identification, when possible, can take decades. It should also be noted that it is possible to have a classification of combined, for example when a plane crashes on a populated area killing people of the ground as well as those in the plane.

Management of Disaster Victim Identification

Interpol recommends that each member state should establish a permanent DVI team, with pre-planning and training for disasters. In planning for and following a disaster multiple facets of the DVI operation have to be considered, for example: initial assessment of the scope of the disaster, mapping and searching of the affected area, estimating the number of victims and degree of fragmentation, methodology to recover and transport the corpses, methodology to be used for identification, and identifying the individuals/medicolegal institutes that are to be involved in the identification process. The criteria that must be met before identifications are made must also be agreed upon prior to bodies being released to families – this becomes increasingly important with increasing numbers of victims as this augments the probability of incorrect identifications.

Another important decision is the scope of the identification process, that is, with fragmented remains what will the operation aim to identify – whole bodies only, recognizable body parts, body parts of a specific size? In cases of extreme fragmentation (e.g., plane crashes) or disruption of primary

burials into secondary and even tertiary mass burials (e.g., Bosnia), it is also necessary to have a policy in place regarding how relatives of the missing will be informed when a portion of their missing person has been identified. Through this policy, relatives of the missing may, for example, elect to be notified when (1) the entire identification process has been completed and all the remains identified of the individual are collected and returned at a single time; (2) the first body part has been identified; or (3) every time a body part has been identified. This allows the relatives of the missing to assert some control over their relationship to the identification process and also decide at which point they wish to hold memorial and/or funeral services.

Principles of Identification

Identification of individuals killed in mass disasters and conflicts should be held to the same standards as identification of individuals killed (or found dead) under any other circumstance. The processes used in identifying individuals must be robust and the families of the missing must have confidence in the identification process. Decisions regarding the methods of identification to be employed are influenced by the condition of the victims, personnel involved in the identification, resources, and technology, as well as by the availability of AM comparatives. There are four widely recognized means of positive identification, whereby a single method alone can be used to make an identification; all others must be regarded as a means of presumptive identification, which can be used to support identification or generate further leads to identity, but may not in themselves 'make' an identification. Fingerprints, dental/medical records (including radiographs), nuclear DNA, and unique medical identifiers are all means of primary positive identification. Visual recognition (of tattoos,

facial features, birth marks, scars, etc.), a matching biological profile generated by forensic anthropologists (age, sex, race, stature, and AM trauma/pathology), matching medical conditions identified by pathologists, facial superimposition, matching personal effects and clothing, matching identification documents, exclusion (when, for example, there is only one child among the victims) and/or matching mitochondrial DNA (mtDNA) profiles are secondary means of identification, ideally for use in support of the primary methods (Figure 1).

Methods of Identification

Objective Methods

Objective methods, sometimes referred to as scientific methods, if applied appropriately, can give unambiguous identifications.

Fingerprints

Identification of individuals through fingerprints is a well-established scientific method, and is routinely used worldwide. In humans, the palms and fingers are covered in skin that is thickened with ridges that helps to grip surfaces (friction ridge skin); the soles of the feet and toes are also covered with friction ridge skin. Friction ridge skin is considered to be unique and over the last 100 years of application, with millions of fingerprints used for forensic identification, only a handful of issues of misidentification have been reported, making fingerprints a powerful means of identification; importantly fingerprints remain unchanged throughout life, other than through scarring.

Several systems have been developed to classify fingerprints, all of which are based on categorization of the overall pattern, that is loops, arches, and whorls, and then identification of distinct combinations of features within the pattern,

Figure 1 Identifications obtained using visual recognition or other customary means are, where possible, supported by comparing antemortem and postmortem data to allow biological profiling and collection of additional evidence to support the identification. Ideally, identifications should be supported by at least one form of scientific identification, which greatly reduces the possibility of misidentification. *, SNP-based DNA analysis could also provide scientific identification but is not widely used; **, scientific identification using odontology would normally require comparison of dental radiographs or other features that would be considered to be unique.

such as bifurcations, lakes, and ridge endings. Its utility to DVI identification varies from case to case. The remains have to be fleshed and in a state of preservation that allows for prints to be taken – this may be possible even with partially decomposed and even burned remains, as fingers curl inward when exposed to fire, thus preserving the ridge details.

As with all other forms of identification, AM records also need to exist for comparison. Whether extensive AM records are available varies depending on the country or countries involved; many countries collect fingerprints from all of its citizens once they reach adulthood and this information is typically held in a national computer, which allows rapid searching – in other countries legislation may prevent the storage of fingerprints, or restrict it to those arrested in connection to a criminal offence. If no AM records are available, it may be possible to recover AM prints from the personal possessions of the missing person(s), assuming there is reliable information on who is actually missing. With a computer-based search using an automated fingerprint identification system (AFIS), a list of candidate matches can be produced in seconds; however, the algorithms are not sufficiently refined to produce exact matches and computer-generated matches have to be examined manually by an expert to establish a confirmed match.

Dental radiographs

The identification of individuals based on a comparison of AM and postmortem (PM) radiographs is, arguably, a somewhat subjective process, but one which is nonetheless recognized as a scientific means by which a positive identification may be made. While in the past, radiographic equipment may not have been available *in situ* and radiographers were forced to ship bulky equipment and improvise darkrooms in which to develop the films, this is no longer an obstacle. Portable digital radiographic equipment – some even hand-held – is widely available, and rapidly becoming cost-effective. If not available in the country in which the disaster or conflict has occurred, this equipment is so portable that it can be carried as hand luggage in the passenger compartment of aircraft deploying individuals to the scene.

The AM–PM matching of radiographs for identification is more widely accepted in forensic dentistry than in forensic anthropology, where the former is most often based on radiographic images of dental restorations and/or implants, which evince the unique characteristics of both the morphology of the lesion and that of the dentist's individual technique and thus afford multiple surfaces for examination (Figure 2), the latter relies upon matching frontal sinus, cranial sutures, vertebral morphology, and even bone trabecular patterns, not just the orthopedic equivalent of implants, fixators, pins, plates, screws, and artificial joints. Although the angle at which an AM radiograph is taken may cause distortion, elongation, and superimposition of features in a dental radiograph, the problem is often compounded in an orthopedic image by additional factors such as age-related changes in joint surfaces and trabecular re-alignment caused by the application of differing stresses due to activity level and type with age. In all radiographic comparisons, the years elapsed between when the AM image was made and the individual's death must be taken into consideration. Superimposition of the AM–PM images of restorations is a frequently used technique in conjunction with

Figure 2 (a) Antemortem orthopantomogram, (b) postmortem mandibular, and (c) maxillary radiographs from the same individual (Radiographs courtesy of Dr John Robson).

the correspondence of measurements. Again, there is somewhat better correspondence within dental images than even within internal fixators used in fracture repair, as remodeling of bone due to weightbearing contributes to the movement of implanted devices over time. Dental records themselves (e.g., notations of teeth treated, condition of teeth, etc.) are not definitive in DVI as both omissions and mistakes in recording do occur however, such records are potentially useful when comparing large numbers of AM and PM records to establish possible matches and in providing additional support for an identification; in some contexts dental records are used when radiographs are not available.

The utility of dental radiographs tends to be limited to developed countries where individuals typically visit the dentist and radiography is commonly used as part of routine examinations or following any major dental work. The dentist normally keeps either the developed radiographs themselves, microfilm of those radiographs, or stores digital radiographic images in the patient's electronic file. When disaster victims have not been subjected to trauma that has resulted in disruption of the dentition and AM records are available, forensic odontology is a powerful means of achieving identifications.

Nuclear DNA

Since its introduction into forensic science in 1985, DNA profiling has become commonplace in forensic laboratories worldwide. Its primary forensic use is for the identification material recovered from scenes of crimes; however, it is also widely used in the identification of human remains, particularly following on from transport disasters, such as plane crashes.

By the early to mid-1990s, the analysis of short tandem repeats (STRs) had replaced variable number tandem repeat (VNTR)-based analysis. STRs had several advantages: they could be analyzed using polymerase chain reaction (PCR)-based methods, which made them much more sensitive; the alleles of STR loci are also much shorter, making the analysis of degraded material easier; several STR loci could be analyzed in

one reaction and analyzed together using capillary electrophoresis (CE), which greatly reduced the time taken to carry out the analysis; and the profiles could be broken down into a series of numbers corresponding to the number of core repeats present in each allele, which allows comparisons to be made between DNA profiles generated within a laboratory and also to compare profiles generated in different laboratories.

STRs are found throughout the genome and they are composed of short blocks of sequence that are repeated in tandem – the STRs commonly used for forensic analysis have blocks of sequence that are 4 or 5-bp long (Figure 3). While there are numerous STR loci in the human genome that could be used as forensic markers, around 20–25 are commonly used. These have been selected for being highly discriminating (typically having a large number of variants (alleles) that differ in the number core repeats) and for being easy to analyze using PCR-based technology. Using current methodology DNA profiles can, in principle, be generated within a few hours and produce a profile that is extremely rare, if not unique (Figure 4).

Because of the limited discrimination capacity of the early profiling systems, it was not until 1991 that DNA profiling was successfully employed in the identification of human remains – in this case, a murder victim in the UK. It has since been successfully applied to cases that range from the identification of

individual bodies to more complex scenarios with multiple victims following, for example, air crashes, fires and explosions, terrorist attacks, natural disasters, and conflicts. A distinct advantage of DNA analysis in DVI is that all tissues contain DNA, and therefore the method will work on highly fragmented remains and enable fragments of bodies to be re-associated.

As with the other forms of identification, the use of DNA analysis in DVI will vary from context to context. Whether DNA can be recovered from the human remains depends on the degree of environmental insult, for example, if the remains have been subjected to high temperatures in excess of 200 °C or there has been a long delay in locating and recovering the remains the DNA can be highly degraded, and it may not be possible to generate a profile. AM data is required for comparison: this can be in the form of a direct comparison if a biological sample from the missing person is available, or more commonly by comparison to biological relatives of the missing person.

Unique medical identifiers

On occasions, PM analysis of human remains may happen upon a medical implant; typical examples are artificial joints and pacemakers. These medical devices come with a unique serial number and can allow for unambiguous identification as

Figure 3 The structure of a short tandem repeat. This example shows the structure of two alleles from the locus D8S1179. The DNA either side of the core repeats is called flanking DNA. The alleles are named according to the number of repeats that they contain – hence alleles 8 and 10.

Figure 4 A DNA profile is represented by a series of peaks that can be broken down into a numerical code – the numbers correspond to the number of core repeats in each STR allele. The profile above contains the information on ten STR loci and the amelogenin locus, which differentiates between the X and Y chromosomes – in this profile, labeled X and Y (showing that this DNA sample is from a male).

long as the relevant information can be located. Needless to say, identifications through this method are not common.

Data Collection

Data collection, both PM and AM, is a critical component of the DVI operation. Several agencies, both national and international, have developed forms that facilitate the systematic collection of data that can be used in the identification process. The most commonly employed system for DVI work uses the Interpol forms – these have been specifically developed for DVI work. The International Committee of the Red Cross (ICRC) has also developed AM and PM forms, which have been designed for use in post-conflict scenarios (Figure 5). Both these systems can be computerized with the data entered into a relational database, allowing AM and PM data to be cross-searched. National authorities have also developed their own systems, for example, in the US, the Disaster Mortuary Operational Response Team (DMORT) has its own set of recording forms and database recording similar information. Obviously, the more victims and the greater the fragmentation of those individuals, the more imperative it is to computerize PM and

AM records. Searching by hand through records for matches, especially when the personnel who originally recorded PM details are no longer available and memory is lacking, is a frustrating exercise.

Postmortem

The cooperation and teamwork of experts, sharing of information, and agreement concerning and adherence to criteria by which an identification will be made, are critical to the management and effective performance of any DVI team. The work flow in the morgue, and hence floor plan, should be arranged to facilitate the processing of remains as well as the communication among the various teams of experts. The technical experts involved in the collection of data will vary depending on the state of the human remains; typically teams will comprise some or all of a pathologist, who will undertake a PM examination; an anthropologist to examine skeletal material; an odontologist to take radiographs and examine the teeth; a radiographer to take whole body X-rays; a fingerprint expert; and a biologist to take samples for DNA analysis. Other individuals, for example police officers and crime scene investigators, will also be involved carrying out tasks such as documenting personal

Dental treatment: Has the missing person received any dental treatment such as ▪ Crowns, such as gold-capped teeth ▪ Color: gold, silver, white ▪ Fillings (incl. color if known) ▪ False teeth (dentures)-upper, lower ▪ Bridge or other special dental treatment ▪ Extraction Also indicate wherever there is uncertainty (for example, the family member may know that an upper left front tooth is missing, but is unsure which one).	If possible, use a drawing, and/or indicate the described features in the chart below If the missing person is a child, please indicate which baby teeth have erupted, which have fallen out and which permanent teeth have erupted and use the chart below <table border="1"> <thead> <tr> <th data-bbox="584 1323 893 1354">Baby/Primary teeth</th> <th data-bbox="893 1323 1286 1354">Adult/Permanent teeth</th> </tr> </thead> <tbody> <tr> <td data-bbox="584 1354 893 1871"> Top  Bottom </td> <td data-bbox="893 1354 1286 1871"> Top  Bottom </td> </tr> </tbody> </table>	Baby/Primary teeth	Adult/Permanent teeth	Top  Bottom	Top  Bottom

belongings, clothing, taking photographs, and ensuring chain of custody for any evidential items.

Antemortem

A prerequisite to the application of any of these methods is the existence of relevant, reliable AM data. Following a mass disaster, an AM data collection interview is typically conducted with relatives of the missing. The collection of AM data is as much a specialized process as conducting a PM examination, and interviews of relatives of the missing should be performed only by trained personnel. Interviews are best performed by native speakers of the language, so in-country training of personnel should be planned. During the interview, information concerning the individual's physical description, a description of the clothing the individual was wearing, and any personal effects that were with the individual are recorded on an AM data form – this form should be compatible with the PM form to allow searching of comparable fields of information. A photograph of the missing person is collected and the existence and whereabouts of medical and dental records for that individual are noted so that these can be requested from doctors and dentists at a later date. Photographs of the victim's smiling can be also be useful as the teeth may have distinguishing morphology or features such as spots caused by hypoplasia. During this interview, if possible, DNA samples are taken and latent fingerprints are enhanced and collected from the home of the missing person. DNA samples may be direct reference samples (e.g., from the missing person's toothbrush or hairbrush) or indirect reference samples, preferably from their immediate kin (father, mother, children).

The above methods work very well in developed countries and the process above describes the situation in a country with well-developed infrastructure. However, the infrastructure of many less-developed countries does not facilitate the collection, maintenance, and storage of such relevant records that drive the DVI process for the citizenry of developed countries. In post-conflict situations, even where such records may have existed at one time, they may have been destroyed during the conflict or its aftermath or have become unavailable due to political and boundary shifts. In natural or other mass disasters in less-developed countries, the same may be true regarding destruction of extant records or the lack of relevant records. Furthermore, subsequent to mass disasters and conflicts many individuals are frequently displaced internally or have become refugees in neighboring countries. This makes locating relevant kin of the missing difficult, and organizing and conducting AM interviews challenging. Whenever possible, it is recommended to avoid re-traumatizing the relatives of the missing by repeated visits and questions, as these doubtless re-open wounds, doubts, and raise anxiety.

Selection of Methods for Identification

In any mass disaster, the method that can be employed successfully will be dictated according to the condition of the remains, the composition of experts in the DVI team, the technical and financial resources available, and the choices made by the team's leadership during the course of its operational mandate.

Prior to DNA analysis, comparison of dental records was the most widely used method to achieve identifications. Analysis of

five disasters in the UK between 1985 and 1989 which comprised three air disasters, a capsized ferry, and a fire on an oil platform, identified that dental records had been used to identify, on average, over 80% of the recovered bodies. In more recent large-scale disasters, for example, in the World Trade Center investigations, DNA was the first choice for identification and generated the majority of identifications by a single modality (86%), dental and fingerprints combined only yielding an additional 10% of identifications. Similarly, since the inception of the International Commission for Missing Person's (ICMP) DNA laboratory in Tuzla (Bosnia), identifications from the 1992 to 1995 Bosnian conflict have been DNA-led, with secondary means of identification used, where possible, to support the DNA-based identification – as of mid-2011, over 13 000 individuals in Bosnia and Herzegovina had been identified and returned to their families. In contrast, although DNA was initially a method of first choice in the Asian Tsunami identifications in Thailand, 11 months after the tsunami 80% of foreign victims had been identified using dental comparisons – dental analysis with local victims identified 55% of Thai victims, lower than with foreign victims due to the lack of AM records in many cases. Overall, in the 15 months following the disaster, identifications had been made using: dental alone, 1105; dental plus others, 1451; fingerprints alone, 670; fingerprints plus others 927; DNA alone, 27; DNA plus others 459.

There are reasons for the success ratios of the identification methods in each of the above examples. In the World Trade Center, victim fragmentation was extreme and the goal was set to identify every piece of tissue greater than or equal to 5 cm³, thus necessitating the use of DNA. In Bosnia, lack of AM medical and dental records, commingling in secondary mass graves, and time elapsed since the deaths of the victims are but a few of the factors that dictated the reliance on DNA rather than other primary identifiers. In Thailand, important factors included that dental-based identifications could be made for many of the foreign victims relatively rapidly; many bodies were not fragmented, removing the requirement for DNA-based re-association; fingerprint analysis was successful with many Thai victims; limited in-country facilities were capable of handling the volume of DNA samples from the disaster; and decomposition of tissue was rapid in the tropical environment, making DNA analysis difficult.

Evaluation of Identification Data

The exact procedures used in the identification process vary from country to country and from scenario to scenario. Typically, identifications are made through an organization that acts as an identification commission or board; this would typically include an expert from the main disciplines involved in making identifications – investigators/crime scene investigators, fingerprint examiners, odontologists, pathologists, anthropologists, and DNA analysts – and should be presided over by the legal authority charged with issuing death certificates. In this manner, all the evidence contributing to the identification of an individual in a mass disaster is reviewed a final time by everyone who has contributed to that process, and a legal decision concerning the establishment of positive identity and repatriation of the remains to kin can be completed.

Evaluating the identification is a complex task, especially as the number of victims increases – this heightens the possibility of coincidental matches, which, if not detected, can lead to misidentifications. An often cited example where this occurred is the identification of a fire officer recovered from the World Trade Center following 9/11, who was misidentified on the basis of his clothing that identified him as a fire officer from a particular unit coupled with a rare congenital anomaly in spinal vertebra. The identification was not confirmed by any of the recognized objective methods of identification and DNA analysis later exposed the misidentification, but only after the remains had been returned to the wrong family – the rare medical condition had been shared by one of his colleagues in his unit. Such seemingly remote coincidences become more likely as the number of victims increases.

Conclusions

The requirement for governments and indeed the international community to be able to mount an effective DVI response following disasters and conflicts is widely accepted. Recent technological advances in terms of DNA analysis, portable radiographic equipment, and sophisticated computer databases that allow comparison of AM and PM data have increased the number of cases where the identification of human remains is possible. There will always be limitations as to what is possible; for example, following the World Trade Center identifications, even with an enormous effort expended, no identification could be made for over 40% of the victims, which should not distract from the success in identifying over 1500 victims. With continued improvements in technology, preparedness, and infrastructure to deal with a large number of samples in a timely fashion, there is the potential to have a greater proportion of victims identified and returned to their families following future disasters and conflicts.

Forensic DNA Advisory Groups: DAB, SWGDAM, ENFSI, and BSAG

JM Butler, National Institute of Standards and Technology, Gaithersburg, MD, USA

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Quality assurance A system of activities whose purpose is to provide confidence to the producer or user of a product or service that it meets defined standards or quality.

Validation The process by which a method, instrument, or computer program is deemed useful for a specified purpose through rigorous evaluation before acceptance into routine use.

Introduction

With a technique as powerful as forensic DNA testing to help establish guilt or innocence in the context of criminal investigations, it is imperative that measures are in place to create confidence in the results obtained. This article provides a brief review of national- and international-level organizations that support the forensic DNA community in an advisory capacity to promote accurate and reliable testing and to assist with quality assurance measures. [Table 1](#) includes a summary of the major national or regional groups that govern or coordinate efforts with forensic science. [Table 2](#) lists some details regarding the forensic DNA advisory groups that will be covered in this article.

The United States

Concerns regarding data quality as forensic DNA testing that began to spread in the first decade of its use led to the formation of several organizations within the United States. In addition, reports by the National Research Council of the US National Academies of Science in 1992 and 1996 focused on technical and statistical issues surrounding high-quality DNA results.

The Technical Working Group on DNA Analysis Methods/the Scientific Working Group on DNA Analysis Methods

The Technical Working Group on DNA Analysis Methods (TWGDAM) was established in November 1988 under FBI Laboratory sponsorship to aid forensic DNA scientists in North America. Since 1998, TWGDAM has been known as SWGDAM, which stands for the Scientific Working Group on DNA Analysis Methods. SWGDAM is a group of approximately 50 scientists representing federal, state, and local forensic DNA laboratories in the United States and Canada. A representative of the European Network of Forensic Science Institutes (ENFSI) DNA Working Group often attends as well. Meetings are held twice a year, usually in January and July. For several years, public SWGDAM meetings were held in conjunction with the International Symposium on Human Identification, sponsored each fall by the Promega Corporation. Since 2006, the public SWGDAM meeting has been held as part of the FBI-sponsored National Combined DNA Index System (CODIS) Conference.

Since the organization's inception, six individuals have served as TWGDAM or SWGDAM chair: James Kearney (FBI),

Bruce Budowle (FBI), Richard Guerrieri (FBI), David Coffman (Florida Department of Law Enforcement), and Ted Staples (Georgia Bureau of Investigation). In January 2011, Anthony Onorato (FBI) was appointed by the FBI Laboratory Director to be the chair of SWGDAM.

Over the years, a number of TWGDAM or SWGDAM Committees have operated to bring recommendations before the entire group. These Committees have included (at different times) the following topics: restriction fragment length polymorphism, polymerase chain reaction, CODIS, mitochondrial DNA, short tandem repeat (STR) interpretation, training, validation, Y-chromosome, expert systems, quality assurance, missing persons/mass disasters, mixture interpretation, mass spectrometry, enhanced method detection and interpretation, and rapid DNA analysis. TWGDAM issued guidelines for quality assurance in DNA analysis in 1989, 1991, and 1995. Revised SWGDAM validation guidelines were published in 2004 and interpretation guidelines for autosomal STR typing were released in 2010. Several ad hoc working groups have produced recommendations on such topics as the review of outsourced data and partial matches. SWGDAM documents are made available through *Forensic Science Communications*, an online journal sponsored by the FBI Laboratory.

DNA Advisory Board

The DNA Advisory Board (DAB) was a congressionally mandated advisory board that was created and funded by the United States Congress through the DNA Identification Act of 1994. The first meeting of the DAB was held on 12 May 1995, and chaired by Nobel laureate Dr Joshua Lederberg. The DAB consisted of 13 voting members that included scientists from federal, state, local, and private forensic laboratories; molecular geneticists and population geneticists not affiliated with a forensic laboratory; a representative from the National Institute of Standards and Technology (NIST); the chair of TWGDAM; and a judge.

The original voting members of the DAB included Joshua Lederberg (Rockefeller University), Arthur Eisenberg (University of North Texas Health Science Center), Shirley Abrahamson (Wisconsin State Supreme Court), Jack Ballantyne (Suffolk County Crime Lab), Bruce Budowle (FBI Laboratory), Ranajit Chakraborty (University of Texas Health Science Center), Bernard Devlin (Carnegie Mellon University), Marcia Eisenberg (Laboratory Corporation of America), Paul Ferrara (Virginia Division of Forensic Science), John Hicks (Alabama

Table 2 Forensic DNA advisory groups

<i>Organization</i>	<i>Membership</i>	<i>Meeting frequency/purpose</i>
DNA Commission of the International Society for Forensic Genetics (ISFG)	ISFG Executive Committee and selected experts; chaired by Dr. Peter Gill	As needed to prepare recommendations (see http://www.isfg.org/Publications/DNA+Commission)
Scientific Working Group on DNA Analysis Methods (SWGDAM)	US and Canada federal, state, and local DNA Technical Leaders and invited guests (40–50 people total); subdivided into 5–8 committees	Meets twice a year to develop guidelines on validation, DNA data interpretation, and other topics
European Network of Forensic Science Institutes (ENFSI) DNA Working Group	>30 European countries and invited guests (90–100 people total); subdivided into five committees	Meets twice a year along with European DNA Profiling Group (EDNAP)
Biology Specialist Advisory Group (BSAG)	Representatives of each forensic DNA lab in Australia and New Zealand (11 people total)	Meets once a year under direction of SMANZFL and with support of the Australian National Institute of Forensic Science

Department of Forensic Sciences), Margaret Kuo (Orange County Sheriff's Office), Terry Laber (Minnesota Bureau of Criminal Apprehension), and Dennis Reeder (NIST). Non-voting members of the DAB were Phillip Reilly (Euince Shriver Center for Mental Retardation), Larry Presley (FBI Laboratory), Jay Miller (FBI Laboratory), and Randall Murch (Designated Federal Employee, FBI Laboratory). A number of other individuals attended and participated in various DAB meetings over the 5 years that the group met.

The DAB was created for a 5-year period to issue quality assurance standards (QAS) for the forensic DNA community. When the DAB's responsibilities ended in 2000, SWGDAM was designated as the group responsible for offering recommendations on revisions to the QAS as needed. In 2007, SWGDAM revised the QAS for Forensic DNA Testing Laboratories and the QAS for DNA Databasing Laboratories. These revised standards went into effect on 1 July 2009 after being approved by the FBI Laboratory Director. Further revisions regarding data review were made at the January 2011 SWGDAM meeting and went into effect on 1 September 2011.

Forensic DNA laboratories in the United States are mandated by Congress to follow strict QAS. In October 1998 and April 1999, at the recommendation of the DAB, the FBI Director issued QAS for Forensic DNA Testing Laboratories and QAS for Convicted Offender DNA Databasing Laboratories that

define how forensic laboratories are required to conduct business. These QAS were revised a decade later and went into effect on 1 July 2009, with some additional minor revisions introduced in 2011 regarding data review. The 2009 revisions also renamed the Convicted Offender QAS as the QAS for DNA Databasing Laboratories so that they would be applicable for laboratories processing offender, arrestee, and detainee specimens. US forensic DNA laboratories are governed by the QAS and regularly audited for their compliance to these standards.

There are 17 topics covered in the revised (and original) QAS: (1) scope, (2) definitions, (3) quality assurance program, (4) laboratory organization and management, (5) personnel, (6) facilities, (7) evidence/sample control, (8) validation, (9) analytical procedures, (10) equipment calibration and maintenance, (11) reports/documentation, (12) review, (13) proficiency testing, (14) corrective action, (15) audits, (16) safety, and (17) outsourcing.

The American Society of Crime Laboratory Directors and Its Laboratory Accreditation Board

The American Society of Crime Laboratory Directors (ASCLD) and its Laboratory Accreditation Board (ASCLD/LAB) play an important role in the United States as well as internationally for laboratory accreditation programs. The ASCLD/LAB motto

is 'quality assurance through inspection.' The crime laboratory accreditation program is a voluntary program in which any crime laboratory may participate to demonstrate that its management, operations, personnel, procedures, and instruments meet stringent standards. The goal of accreditation is to improve the overall service of forensic laboratories to the criminal justice system. If a forensic laboratory is interested in becoming accredited, an ASCLD/LAB accreditation manual is available from the Executive Secretary for a fee. Laboratories becoming accredited in forensic biology are audited against the FBI's QAS for the laboratory operations pertaining to DNA testing. ASCLD/LAB accreditation may be under the Legacy Program or the International Program. However, no new Legacy Program applications have been processed since April 2009. Laboratories are being supported under the Legacy Program until they can transition to ASCLD/LAB-International, which accredits to ISO/IEC 17025 requirements. As of September 2011, a total of 389 crime laboratories were accredited by ASCLD/LAB although not all of them are doing DNA testing. For additional information see ASCLD/LAB website.

Forensic Quality Services

Forensic Quality Services, Inc. (FQS) is a not-for-profit organization providing ISO/IEC 17025 accreditations to forensic testing laboratories in the United States. FQS is recognized by the FBI to perform QAS DNA assessments and offers training workshops on accreditation. For more information see FQS website.

Europe

As with the United States, organizations have been in place in Europe since the late 1980s to help with forensic DNA analysis.

DNA Commission of the International Society for Forensic Genetics

The International Society for Forensic Genetics (ISFG) is an organization of over 1100 scientists from more than 60 countries promoting scientific knowledge in the field of forensic markers from human blood. Since 1989, the ISFG has issued recommendations on a variety of important topics in forensic DNA analysis through a DNA Commission. These recommendations have included naming of STR variant alleles and STR repeat nomenclature, mitochondrial DNA and Y-STR issues, DNA mixture interpretation, paternity-testing biostatistics, disaster victim identification, and use of animal DNA in forensic genetic investigations. For more information see ISFG DNA Commission website.

European DNA Profiling Group

Another working group of the ISFG is the European DNA Profiling Group (EDNAP), which consists of members from 21 laboratories across 17 European countries along with a few invited guests from the United States and Australia. Niels Morling from Denmark is the chair of EDNAP, whose members

are from university Institutes of Legal Medicine and government forensic laboratories with a focus on research. Currently, Austria, Belgium, Denmark, England, Finland, France, Germany, Greece, Ireland, Italy, the Netherlands, Norway, Portugal, Scotland, Spain, Sweden, and Switzerland are represented.

EDNAP was established in October 1988 with a goal to harmonize methods used to aid forensic DNA investigations. EDNAP meets twice a year (since 2004 in conjunction with ENFSI DNA working group meetings) and regularly organizes collaborative exercises to assess methods and examine where improvements can be made. These interlaboratory studies are published in the scientific literature and have helped establish European core loci and address new marker systems (see ISFG website). The Institute of Legal Medicine in Innsbruck, Austria, has developed and maintains the EDNAP Mitochondrial DNA Population Database (EMPOP). For more information see EDNAP website.

The European Network of Forensic Science Institutes

The ENFSI was formally started in 1995 to set standards for exchange of data between European member states and to be an accrediting body through conducting laboratory audits. Today ENFSI is recognized as the sole voice of the forensic-science community within Europe. Within the ENFSI, there is a DNA working group that meets twice a year to discuss forensic DNA protocols and research in much the same fashion as SWGDAM does within North America.

The ENFSI DNA working group has five committees referred to as 'workshops': (1) quality control, quality assurance, sampling kits, training, and teaching; (2) DNA analysis methods and interpretation; (3) DNA databases; (4) automation and expert systems; and (5) forensic biology. Manufacturers are permitted to participate in many of the meeting sessions and are given an opportunity to share information on their latest products.

The database committee produces an annual document on DNA database management that in April 2010 included 28 recommendations (audit questions surrounding these recommendations have been added in more recent versions). Reports and surveys of DNA database sizes in Europe are regularly conducted and shared through the ENFSI website. Recommendations for training of DNA staff and minimum validation guidelines were released in November 2010. An ENFSI collaborative project on Y-STR analysis of DNA mixture samples was published in 2008 and a statement issued regarding European consensus regarding DNA mixture interpretation principles was published in conjunction with EDNAP in 2007. The ENFSI DNA working group maintains a population database for determining match probabilities across European populations at their website.

Chairs of the ENFSI DNA working group have included Dave Werrett and Lyn Fereday from the UK Forensic Science Service and Ingo Bastisch from Germany's BKA (Bundeskriminalamt). Members of ENFSI come from Austria, Belgium, Bosnia and Herzegovina, Croatia, Cyprus, the Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Ireland, Italy, Latvia, Lithuania, Montenegro, the Netherlands, Norway, Poland, Portugal, Russia, Slovakia, Slovenia, Spain, Sweden, Switzerland, Turkey, and the United Kingdom. Invited guests

from the United States, Abu Dhabi, and Australia regularly attend as well. For additional information see ENFSI website.

Spanish- and Portuguese-Speaking Countries

The Academia Iberoamericana de Criminalística Y Estudios Forenses (AICEF) serves Spanish- and Portuguese-speaking countries in Europe and Latin America and has 32 active members from 19 different countries. There are four working groups in AICEF: crime scene (CITEC), forensic genetics (GITAD), ballistics (CITBAF), and drugs of abuse (GITADA). For more information see AICEF website.

Australia/New Zealand

The National Institute of Forensic Science

The National Institute of Forensic Science (NIFS), which is located in Melbourne, began in 1992 as a central organization to serve the forensic-science community in Australia and New Zealand. NIFS sponsors and supports research in forensic science, assists with development and coordination of forensic-science services between jurisdictions, aids training programs, and coordinates delivery of quality assurance programs. In 2008, NIFS became a directorate in the newly formed Australia New Zealand Policing Advisory Agency. NIFS works closely with the Senior Managers of Australia and New Zealand Forensic Science Laboratories (SMANZFL). For more information see NIFS website.

The Senior Managers of Australia and New Zealand Forensic Science Laboratories

The SMANZFL are the directors from forensic-science organizations in Australia and New Zealand who meet at least once a year in an effort 'to promote leadership in the forensic sciences in the pursuit of excellence.' SMANZFL is supported by eight specialist advisory groups covering biology, chemistry, document examination, field and identification sciences, toxicology, illicit drugs, and electronic evidence. For more information see SMANZFL website.

Biology Specialist Advisory Group

The Biology Specialist Advisory Group (BSAG) is one of the eight SAGs of SMANZFL and is funded by NIFS to prepare recommendations for their laboratories. BSAG meets formally once a year but also holds additional meetings in person or through the Internet as needed. The BSAG has representatives from 11 organizations within Australia and New Zealand: Victoria Police Forensic Services Centre, Victorian Institute of Forensic Medicine, New South Wales Institute of Forensic Medicine, New South Wales Police Forensic Services Group, Queensland Health, Northern Territory Police Forensic Services, Western Australia's PathWest, Forensic Science South Australia, Forensic Science Service Tasmania, Australia Federal Police, and New Zealand's ESR (Environmental Science and Research). Pam Scott of the Forensic Science Service in Tasmania is the current BSAG chair. BSAG has written in support of the ISFG DNA Commission recommendations on DNA mixture

interpretation and disaster victim identification. For more information see BSAG website.

Asia

The Asian Forensic Sciences Network (AFSN) is the most recent regional organization formed in support of forensic sciences. Created in 2008, AFSN has five workgroups covering DNA, illicit drugs, toxicology, trace evidence, and quality assurance and standards. AFSN meets annually. As of September 2011, member institutes include representatives from Brunei Darussalam, Indonesia, Korea, Laos, Malaysia, Mongolia, People's Republic of China, Philippines, Singapore, Thailand, and Vietnam. For more information see AFSN website.

International Cooperation and Coordination

At the international level, there has been a recent effort to have more cooperation across the regional groups listed in [Table 1](#). In 2009, the International Forensic Strategic Alliance (IFSA) was established as a partnership between the regional networks of operational forensic laboratories including ASCLD, ENFSI, SMANZFL, AICEF, and AFSN.

While individual DNA advisory groups like SWGDAM or ENFSI typically produce their own guidelines, there have been a few instances where joint publications have been authored. In 2004, SWGDAM coauthored a position statement on SNP typing, with ENFSI emphasizing that STR markers would likely remain the primary currency for national DNA databases for the foreseeable future. In 2010, SWGDAM joined with ENFSI and BSAG in a position paper on consumable contamination concerns and potential solutions for manufacturers and consumers. This topic is continuing to be pursued through an international effort that will hopefully lead to a formal ISO (International Standards Organization) standard for forensic-grade DNA-free products.

Acknowledgments

Review of this article by Dawn Herkenham and Linzi Wilson-Wilde is greatly appreciated. Forensic DNA research conducted at NIST is supported by an interagency agreement between the National Institute of Justice and the NIST Office of Law Enforcement Standards. Points of view in this document are those of the author and do not necessarily represent the official position or policies of the US Department of Justice. Certain commercial equipment, instruments, and materials are identified in order to specify experimental procedures as completely as possible. In no case does such identification imply a recommendation or endorsement by the National Institute of Standards and Technology nor does it imply that any of the materials, instruments, or equipment identified are necessarily the best available for the purpose.

Glossary

Analytical capacity The maximum sample output of analyses a laboratory can produce.

Backlog The number of cases submitted to a crime laboratory for analysis that have not yet been completed, where a final report has not yet been issued.

CODIS (Combined DNA Index System) A term used synonymously with NDIS (National DNA Index System), which is the national DNA database administrated by the United States Federal Bureau of Investigation.

Forensic DNA Analysis of crime scene samples using biological materials to generate profiles and in turn link these to suspect via direct comparison or a match

using a DNA database of profiles from known individuals.

Property crime Offenses committed in which items have been damaged or stolen but no physical harm has caused to an individual.

SANE (Sexual Assault Nurse Education) A program for uniformly training medical staff in the proper treatment of victims of sexual assault, including collection of sexual assault evidence through medical investigation.

UCR (Uniform Crime Reporting Statistics) UCR, collected and reported by the United States Federal Bureau of Investigation, is a compilation of the number of various crimes separated by jurisdiction, type of crime and various other parameters.

Abbreviations

Case One criminal offense and the collective group of evidentiary items and samples emanating from that offense which can be analyzed by a crime laboratory

Item One evidentiary item which can be sampled for analysis by a crime laboratory

Sample One portion of suspected biological material which can be analyzed by a crime laboratory

General

Forensic DNA has the potential to revolutionize the manner in which crimes are investigated. Conventional police wisdom dictates that the first 48 h of an investigation are pivotal for solving a crime, with clearance rates dropping significantly once 72 h have passed. Television crime dramas feature this catchphrase in their titles, including 'The First 48' (Arts and Entertainment Channel). While Cold Case squads are working diligently to challenge this paradigm, it follows that the most investigative resources are applied shortly after a crime is committed as suspects are developed and eliminated. Hence, the costs of conducting police investigations are front-end loaded, as a large amount of resources are exhausted at the earliest stages of the investigation. With typical North American crime lab response times of weeks to months after the commission of the crime, traditional application of forensic science provides objective corroborating evidence but results are frequently insufficiently timely to impact the cost structure of many investigations. In contrast to long response time from crime commission to forensic lab report, the actual analysis time is several hours or days for most types of forensic analyses. The largest component of response time is not the lab analysis itself, but is the time a case sits in a queue behind other cases in a backlog.

In the past, forensic science relied on a suspect sample to be supplied along with the crime scene sample. Serological

analyses took days and early DNA (restriction fragment length polymorphism, RFLP) analysis took weeks for a case to be completed. Hence, investigations were mostly complete along with the development of viable suspects even when cases were initially sent to the crime lab. Now with databases and improvements in forensic technology, a suspect sample is no longer required, and the minimum time for analysis has been reduced to days or even hours. This revolution of analysis speed, sensitivity, and use of information technology to compare millions of suspect profiles to known individuals produces a momentous opportunity. Forensic DNA objectively includes and eliminates suspects and develops new suspects through the DNA databases that traditional investigation may not. Rapid analysis and use of databases can occur with sufficient speed so as to assist investigations at the earliest stages, when the most resources can be focused more quickly on the right suspects while eliminating the innocent from suspicion.

A cursory examination of this situation would indicate if backlogs of cases were eliminated, then case analysis could be quick enough to direct investigations. The reality, however, is that insufficient analysis capacity exists to meet the increasing demands of investigators as they discover that a quicker response is possible. As labs become quicker, more cases are submitted, quickly redeveloping a temporarily reduced backlog.

In order to focus limited resources, many crime labs have taken to limiting the number of analyses per case, items

examined, or do not conduct all analysis types on all cases. Typically, crime labs are not well equipped to project future demand for their service other than to draw on past experience, nor are they able to obtain significant additional resources outside of temporary grant funding. The long-term solution is to accurately forecast the appropriate demand of cases and items and in turn match the crime lab analytical capacity to this projected demand to ensure quick completion of cases without the re-development of backlogs.

The use of forensic technology to solve and prevent crime through rapid analysis will require an investment in lab analytical infrastructure. In order to match analytical capacity to investigative requirements, policymakers must make a conscious decision as to which types of cases and items should be analyzed. This article outlines the forensic potential of case types and samples within cases, as well as demonstrates the value of analyzing property crime cases. Further, a 'Forensic Fire-Station' model is proposed to provide rapid response to case submissions in order to maximize the cost saving through targeting investigations at the earliest stages.

Method

An accurate forecast of demand would enable policymakers to determine the level of resources appropriate for their jurisdiction to turn toward rapid DNA analysis. The Federal Bureau of Investigation compiles detailed statistics for crimes committed in each jurisdiction in the United States, which are provided by the agencies themselves. This undertaking is known as the Uniform Crime Reporting (UCR) program. A study of model crime labs will be used to determine the portion of crimes which are effectively analyzed by forensic DNA technology. Further examination of case types will determine the optimal number of samples per case in order to reduce the demand for analysis to the lowest common denominator of samples, thereby simplifying the balancing of supply to demand.

The number of items submitted per forensic DNA case can vary widely, with major homicide cases and sexual assaults contributing significantly more DNA samples than a simple property crime. While a greater focus should be placed on major crimes against the person, very straightforward small property crime cases can be of great value in apprehending criminals at earlier stages in their career, linking crime trends, or catching a serious criminal in a lesser offense.

Many major crimes are solved through lesser crimes as major criminals frequently commit property crimes as their 'day job.' Analysis of property crimes is much simpler as cases average significantly less samples per case than major crimes. Property crimes have low clearance rates through traditional investigation as there are seldom witnesses, whereas they yield large hit rates using DNA databases. As higher-throughput DNA analysis has developed, cases are placed into a batch process. Lesser crimes with few samples per case can be placed with larger more serious cases in order to round out analytical batches to make best use of resources. Lesser crimes can also work as extra analytical capacity is made available between peaks of major crime demand. With fewer samples per case and larger hit rates on DNA databases, property crimes are very cost effective means of solving crime at a potentially earlier

point in a criminal's career. While property crimes bear fewer samples per case, their connection to major crimes reveals patterns that assist in solving crime sprees. Therefore, a further examination of the breakdown of samples per case will enable a more accurate projection of analytical resources.

Eight high-achieving DNA laboratories were examined and questioned regarding average number of samples analyzed per case. An examination of case submission for these high-achieving labs in relation to the UCR statistics for their jurisdiction was used to determine the ratio of case submissions to crimes committed. The most successful laboratory in this panel of successful crime labs was used as a model with respect to the submission ratio, which is the fraction of the UCR statistics that can be successfully analyzed. Detailed statistics have been developed to calculate an accurate average samples per case submissions for each type of crime. Multiplying the average samples per case for each type of case by the number of cases that can be successfully analyzed produces the number of samples which can be successfully analyzed. Finally, the sample totals for all of the different types of crime are summed to produce the demand for analysis. Once demand for analysis has been forecast, laboratory analytical capacity supply can be designed to meet the demand, hence reaping the maximum benefit from forensic technology.

Laboratory A was analyzed for output and expenses in order to provide a cursory estimate of the level of resources needed to provide rapid DNA service. The Laboratory A Biology Unit case, serology, and DNA sample output per analyst and analysis were collected. Cost savings provided by the laboratory were calculated and then compared to the cost of crime in order to assess the cost-effectiveness of rapid DNA analysis.

As outlined above, there are the four steps in forecasting the number of DNA samples that are cost effectively analyzed in a jurisdiction. First, the number of crimes for each crime type occurring in the region is obtained using the FBI UCR statistics (see Table 1).

In theory, the number of crimes reported represents the maximum number of cases that can be submitted and effectively analyzed by the crime laboratory. Next, examination of the panel of high-achieving crime labs is performed in order to estimate the fraction of each type of case that can be effectively analyzed by the crime laboratory (see Table 2).

The submission ratio gives an idea of the variation in penetration of service found in each crime lab. Clearly, there is a

Table 1 2009 US and laboratory A jurisdiction crimes by type

<i>Crime</i>	<i>Number of offenses in US</i>	<i>Number of offenses in lab A jurisdiction</i>

large gap between crimes committed and the number of cases analyzed in crime laboratories. Not surprisingly, there are a very large proportion of major crimes that are analyzed in all crime laboratories. Crime labs analyze major cases of crimes against the person as a first priority, and then move on to property crimes if there is any analytical capacity remaining. If all labs moved to the submission ratio of their highest high-achieving peer, this estimated increase would provide a starting point toward a forecast of potential future demand for lab analysis.

The submission ratio of homicide cases is above 100% in many crime labs, as demonstrated in [Table 2](#). This is because suicide and attempted homicide case are often submitted, with the outcome of the case unknown until the investigation is completed. Cold cases are also submitted, further increasing the submission ratio. Therefore, it stands to reason that a submission ratio can exceed the FBI UCR statistics for a particular type of crime. Therefore, a target submission ratio of 160% will be used, which is an average submission ratio for the crime lab panel.

In the case of sexual assaults, two of the crime labs have made a particular focus on sexual assaults. Efforts have been coordinated with SANE (Sexual Assault Nursing Education) programs to ensure that all sexual assault cases are collected and analyzed. Also included in these statistics are attempted sexual assaults, thereby increasing the submission ratio above 100%. These labs can serve as a target for other crime labs in terms of a submission ratio projection. Therefore, a target of 110% submission ratio will be used for sexual assault crimes.

For the crimes of assault and robbery, the crime lab panel varied widely. A variety of reasons may underlie the variation, including knowledge base of investigators, acceptance policies of crime laboratories, proximity of investigators to the lab, and their working relationship with the crime laboratory analysts. As a result, the highest achievers will be selected for a target submission ratio. Maine State Police led the panel with a submission ratio of 3.15% for cases of assault; therefore, a target of 3.1% will be used for this crime type. Orange County led the panel with the submission ratio of 7.9% for robbery cases; therefore, 7.9% will be used as a target submission ratio for robberies.

The Orange County Sheriff-Coroner Forensic Science Services was recognized by the National Institute of Justice

(NIJ) through selection as one of six pilot crime labs for a landmark study to determine the potential of using DNA to solve property crimes. The NIJ property crimes pilot project applied to the South Operations patrol area of Orange County with a population roughly one-sixth of the total county. The South Operations patrol area saw submission of 526 property crime cases in a 14-month period, which equates to a 20% submission ratio. Spurring this high submission ratio was training of law enforcement officers coupled with a dedicated police program supervisor. This police supervisor supported training, motivated officers to recognize, collect, and submit burglary evidence, and then followed up by collecting and disseminating success stories. The supervisor also assisted investigators and the lab in targeting those evidence types touched or left behind by perpetrators and those types of items most likely to yield a successful profile. This approach prevented extra work in analyzing items with a low probability of successful DNA analysis. Elimination samples were also collected immediately from home owners, should they have touched items to be examined for suspect DNA to assist interpretation of mixed samples and elimination of nonprobative profiles. In the Orange County Project, DNA profiles are developed in 65% of trace (touch) cases; 45% of it produces a foreign profile that is uploadable to combined DNA index system (CODIS). Once the profile is in the database, the current hit rate is 21% in terms of developing a suspect to aid the investigation.

Motor vehicle theft in particular shows tremendous promise as vehicles are often recovered, and are excellent sources of DNA. Steering wheels, door handles, shift levers, and other touched surfaces are effective targets for fingerprints and trace DNA. With both of these valuable examinations combined as offered by the Orange County Sheriff-Coroner Forensic Science Services, the potential solution rate of this type of crime is exciting. As many car thieves are recidivists and the property damage to stolen cars is very significant, the crime solving and saving potential is very large in dollar terms. Therefore, based on the success of the Orange County pilot, a target submission of 20% will be used for burglaries and auto theft cases.

In the third step, the average number of samples per case type was obtained (see [Table 3](#)). In order to provide a reasonable estimate of the number of evidentiary samples analyzed for each type of case, the panel of crime labs was interviewed

and provided estimates. The Colorado Bureau of Investigation was alone in its keeping of detailed submission data that included samples per type of case. Estimates provided by the other crime labs in the panel independently agreed with the statistics kept by CBI, thereby validating item numbers per case type as seen in Table 3.

As depicted in Table 3, there are approximately 7.5 DNA samples in each homicide case. This contrasts to 5.9 for cases of assault and 4.9 samples for case of sexual assault. Crimes against the person typically have more samples per case than property crimes, as evidenced by 3.5 samples for robbery, 2.7 for auto theft, and 2.1 samples for burglary cases.

In order to project the number of cases, the FBI UCR statistics is multiplied by the submission ratio for each crime type. The number of case samples for each type of case is then calculated by multiplying this projected case total with the average number of samples per case. A grand total of case samples is then found by summing the samples for all the case types. These calculations are demonstrated in Table 4.

Calculating the total potential samples is demonstrated using the crime of robbery as an example. As seen in Table 4, there were 806843 robberies committed in 2009 as per the UCR statistics. If one can forecast the submission ratio as 7.9%,

and the average samples per case at 3.1, then the total forecasted number of samples for robbery cases is 197596. This calculation is conducted for each type of crime, resulting in a grand total of 1953561 samples in order to conduct DNA analysis US wide at the level set by top labs in the high-achieving Lab Panel studied.

While calculating the theoretical total of forensic DNA samples for the US is an interesting exercise, a more practical approach is to apply this method to a single laboratory, which in turn will serve as an example calculation for other jurisdictions. By following this example, jurisdictions may forecast the resources required to match the supply of lab analysis to meet demand for their own area. A hypothetical example using Laboratory A will be used to demonstrate the application of this method to forecast forensic DNA demand.

As noted in Table 5, there were a total of 6776 UCR statistic crimes (not including larceny) committed in the jurisdiction covered by Laboratory A in 2009. Using the submission ratios as dictated in the Crime Lab Panel and the number of samples per case type, the total number of samples projected is 2946 annually.

Once the number of DNA samples has been forecasted, resources required to balance DNA analysis to this demand

Table 3 Colorado Bureau of Investigation Crime Laboratory DNA Section Case Submissions, Lakewood Laboratory (Table demonstrates average number of items and samples per case type)

2007 Submissions	Serology			DNA

can be established. Examination of the number of samples produced per full time casework analyst can be used to determine number of employees required to balance analytical capacity to forecasted demand. **Table 6** depicts the output of two DNA analysts who were dedicated to DNA casework through a year with a small component of additional non-case-related duties.

The average output for the two full-time DNA analysts is 97 cases. These cases were comprised of an average of 247 items analyzed, which in turn yielded 304 DNA samples analyzed. These analysts were selected as their duties focus very largely on casework, whereas other analysts have significant other duties which would skew casework output statistics. It is noteworthy how consistent the output of the two analysts are relative to each other. While a very small sampling of analysts, it is useful as an illustration of methodology to estimate resources required to meet the 2946 sample annual projection.

Estimating the total number of analysts is provided by dividing the projected number of samples by the average output per analyst. Approximately 10 DNA analysts working full time would, therefore, be required to produce this level of output ($2946/304 = 9.7$). Additional tasks conducted in the Biology Unit add overhead, such as accreditation related duties, CODIS administration, QA/QC duties, training, research and development, validation of new technology, and a extra cushion in order to stay ahead of peaks of demand. With a general estimate of 30% overhead, a total staff of 13 would be sufficient to meet full casework potential represented by the crime rate found Laboratory A's jurisdiction. With a population estimate for Laboratory A's area of 971 600 (2009 US Census Bureau, Population Division), this equates to one DNA analyst per 74 738 citizens.

This level of DNA sample projection provides a starting point in order to forecast the level of analytical resources required to meet the overall demand to prevent a backlog from developing and recurring. Addition of resources often comes at the expense of other programs and therefore must be well justified. A calculation as to the cost-benefit or return on investment will provide an illustration of the tremendous value of forensic DNA.

Again, Laboratory A will be used to demonstrate the cost benefit of using forensic DNA to solve and prevent crime. DNA database hits equate to cases where no suspect was developed in a case; hence, DNA was responsible for matching a crime scene DNA profile to the known suspect found in the database. **Table 7** depicts the DNA database hits for Laboratory A from 2002 to 2009.

The Laboratory A Biology Unit has had very good success in providing investigations with new leads on major crimes using

Table 6 Laboratory A annual full time DNA analyst output

	<i>Cases</i>	<i>Items examined</i>	<i>DNA samples</i>

Analyst 2	100	258	318
Average	97	247	304

the CODIS. The savings of investigative time and public safety are intuitively very large; however, they are difficult to quantify. Many cases have suspects and could be solved by conventional means with a greater outlay of investigative time and energy. In cases where the DNA database has matched suspects, no suspect, or a different suspect was named in these cases. As a result, considerable savings are realized in cases with a DNA database match, particularly when the recidivist (repetitive and escalating) nature of crime is factored in. Costs of cases of sexual assault have been quantified and will, therefore, be used to measure the value of the DNA service. The estimated cost of each sexual assault is \$111 238 in terms of damage to the victim, lost time at work, medical cost, and expenses. There were 21 sexual assault DNA database hits in 2010. If one considers the recidivism rate of 8 offenses for rapists, then the saving of the cost of crime is over \$16.35 million annually.

The estimated cost of each burglary is \$1500 in terms of damaged and stolen property. As the top 10% of burglars commit an estimated 232 burglaries apiece annually and some estimates place a career burglar at 200 offenses, a very conservative estimate of 20 offenses will be assumed for an average burglar/robbery offender. There were 28 burglary and 11 robbery CODIS hits for the Laboratory A in 2010 for a total of 39 hits on burglary/robbery cases. The value of these DNA database hits, therefore, translates into a savings of \$1.17 million of the cost of crime annually.

The combined cost-savings of major crime (\$16 350 000) and property crime (\$1 170 000) is \$17 520 000. The cost of the Laboratory A Biology Unit has been calculated to total \$724 794 annually. For each dollar spent, this translates into a savings of \$24.17, or a 2417% return on investment. The savings for property crime alone justifies the DNA program, saving \$1.61 for each dollar spent.

The cost of analysis of a DNA case is the same if it is done within moments of the crime occurring or 6 months later once a case works its way to the front of a backlog. The cost of added resources to provide additional analytical capacity to conduct analysis as soon as a crime is committed is more than offset by the significant return on investment demonstrated. A metaphor is operating a fire station with a backlog of fires

Table 7 Laboratory A CODIS hits by case type

	2002	2003	2004	2005	2006	2007	2008	2009	2010	Total
Murder		1		1			1		1	4
Sexual assault	4	1	8	5	8	4	9	7	21	67
Assault					1				1	2
Robbery	1	1	2	2	1	6	9	8	11	41

Total	5	4	17	9	14	16	47	37	73	222

versus providing sufficient resources to quickly respond to the next fire. The cost and timeliness of the fire dictate a quick response. With the improved speed of forensic DNA and utility of DNA databases, the paradigm has shifted to the point that running a backlog in forensic analyses while a known suspect profile sits in a database is just as wasteful.

Discussion

The cost effectiveness of forensic DNA in solving and preventing crime has been well documented including the analysis of high volume less serious crimes. Crime labs facing large backlogs are more apt to focus on crimes against the person, while lesser offenses such as property crimes are not accepted or are given a lower priority. Increasing lab capacity will improve the response time for major crimes and permit analysis of property crimes, which benefits the system as a whole. A recent project conducted in Denver, Colorado, yielded over \$90 savings in investigative and costs of crime for each \$1 spent. As demonstrated in this study, property crimes typically possess less than half as many samples per case as major crimes, while DNA database hit rates on property crimes are surpassing those of major crimes. Furthermore, property crime has been found to link to violent crime in over 50% of cases, demonstrating that lower prioritization of lesser offenses may hamper investigations as a whole. Therefore, forecasting crime submissions to include property crimes makes good economic and crime-solving sense.

Forensic DNA objectively includes and eliminates suspects and develops new suspects through the DNA databases that traditional investigation may not. Eliminating a large number of suspects conclusively where a crime scene DNA profile from the perpetrator has been developed is a relatively new concept that has been used successfully in a number of major cases, including the homicides committed by Collin Pitchfork and Derrick Todd Lee. Known as 'DNA dragnets', these investigations took advantage of forensic DNA technology's capabilities that are now harnessed in increasingly large databases. With DNA databases now expanding to include lesser offenses as well as arrestees, each crime scene profile is compared to very large numbers of suspects, in essence equaling a dragnet for every case. Legislative efforts coupled with computer technology have brought the power of simultaneous multiple DNA profile comparisons to every agency able to access an accredited crime lab with CODIS capability.

Lives and resources can be saved by analysis of DNA earlier in the investigation of a crime, reducing the time a criminal has available to commit new offenses on additional victims. Stopping a perpetrator early in their career increases the opportunity for intervention and rehabilitation attempts and success. Actual reduction in crime rates can result through the early apprehension of prolific repeat offenders. One prolific burglar admitted to over 1000 offenses. Removing this individual from the population resulted in an immediate reduction in the burglary rate by 40%. Property crimes in particular are highly recidivist offenses, with burglars committing in excess of 200 crimes apiece; hence, an earlier intervention will prevent future crimes.

The cost of a criminal investigation is front-end loaded, in that the majority of investigative resources are spent shortly after the crime occurs. The cost per investigator for a typical police department is estimated to be \$500 per day. Meanwhile, the cost of each DNA sample analyzed has been estimated to be approximately \$500. Correspondingly, if a DNA result can be provided a day earlier the potential cost savings for each investigation will increase. The cost of forensic DNA is the same per case whether done early in the investigation or later once a large proportion of investigative resources have already been expended on a case. Moving forensic DNA analysis to the front end of a case makes sense from crime prevention, investigational, and cost perspectives.

With a return on investment of over 2400% as demonstrated by the calculation with Laboratory A or \$90 per \$1 expenditure in Denver, having cases sit awaiting analysis while investigative resources are spent on suspects that could be easily eliminated with quick DNA analysis is wasteful. An analogy can be drawn between crime labs and providers of services that are critical in terms of response time. Fire service is modeled on quick response, as having a backlog of fires would prove to be disastrous in terms of public safety and loss of property. A backlog of DNA cases is like having a backlog of fires at the fire station. Investigative resources are being rapidly consumed while cases sit awaiting analysis.

DNA cases are currently prioritized in many crime labs, with a constant juggle of backlogged cases as cases are triaged in order to focus rare resources on the most important cases and samples. With additional capacity that is in excess of demand peaks, backlogs can be reduced to near zero. The only cases in backlog would be cases that are currently in analysis, thereby reducing response time to the time actually taken for the lab analysis and reporting itself, which can now

be measured in days. With the backlog of 'fires' now being eliminated, each case would begin processing shortly after arrival at the laboratory. Case processing is typically a batch process, with plates of samples and controls being taken through analytical steps as a unit. By staggering batches by starting them at different points through a week or month, priority cases and samples can be placed on the next batch, with lesser crimes filing in the openings to make best use of available resources. Through accurately forecasting demand and establishing supply just above that demand, prompt response times are assured to reap the maximum benefits of forensic technology. No longer would there be a backlog of fires at the forensic fire station.

Cost savings are not the only benefit of rapid response DNA technology. Potentially less reliable eye witness testimony can be shored up with objective forensic evidence. Forensic DNA evidence increases guilty pleas, increases prosecution rates eightfold, and increases sentences six- to tenfold, thereby also streamlining and increasing the effectiveness of the justice system as well. More victims may also come forward as the pressure to provide testimony is reduced.

Suspect DNA profiles from property crimes not only hit to major offenders, but property crime projects have seen hit rates in excess of 40%. Investigations that utilize DNA benefit with higher identification rates, increasing the identification of suspects from 14% to 44%. The case for conducting forensic DNA analysis on all available types of crime is compelling from a cost and effectiveness standpoint.

Expenditure to provide a measured surplus of forensic analytical capacity is prudent to ensure a rapid response. The surplus of service need not be large, only enough to provide for the peak demand, while lesser calls for service can be handled in the periods of lesser demand. There are a large number of accreditation-related quality control and assurance-related activities, training, validation of new techniques, and the like that can be addressed with resources spared between demand peaks. Analysis of less time critical property crimes has been demonstrated to be a very cost-effective method of ensuring good use of analytical capacity. Accurate projections of case load characteristics will permit balancing of analytical resources to eliminate backlogs and, most importantly, prevent them from occurring, which in turn will ensure prompt response times.

Conclusion

Expansion of forensic laboratory analytical capacity is a significant undertaking that can be performed by each jurisdiction. Using the method provided in this paper provides a forecast of sample demand that can be calculated by multiplying the UCR statistic crimes with the submission ratio and average samples per case type. Once the resources are applied and analytical capacity is in place, forensic backlogs will be eliminated and prevented from recurring. The cost benefit of over 2400% as demonstrated by a sample laboratory provides a compelling case for the financial prudence of focusing investigative resources on the correct suspect at the earliest stages of a criminal investigation.

In summary, while the projection of future submissions of DNA cases in crimes yet to be committed is somewhat speculative, the future of solving crimes with DNA is demonstrably bright. Significant numbers of these cases can be solved, and repeat offenders stopped earlier in their careers. Continued use of DNA on major crimes is projected to remain stable, while growth in sample output will be sustained by property crime cases. Investing in forensic DNA is a wise investment that will pay big dividends in producing more effective investigations and improvements for public safety. Implications have been made regarding the additional cost of lab resources, investigators, and prosecutors that would be required to adequately address projected case demands, posing the question: can we afford to? Conversely, when faced with the demonstrated cost-benefit of solving and preventing crime through forensic technology in human and economic terms, can we afford not to?

Bayesian Networks

Introduction

Almost 30 years ago, Bayesian networks have been developed in the field of artificial intelligence as a framework that should assist researchers and practitioners in applying the theory of probability to inference problems of more substantive size and, thus, to more realistic and practical problems. Since the late 1980s, Bayesian networks have also attracted researchers in forensic science, and this tendency has considerably intensified throughout the last decade. There is now a considerable body of scientific literature that reports on Bayesian networks as a tool that can be used to study, develop, and implement probabilistic procedures for evaluating the probative value of particular items of scientific evidence in forensic science. Within this context, evaluative issues that pertain to forensic DNA profiling evidence hold an important position because this is one of the main categories of evidence whose assessment has been studied through Bayesian networks. The scope of topics is large and includes almost any aspect that relates to forensic DNA profiling. Typical examples are inference of source (or 'criminal identification'), relatedness testing, database searching, and special trace evidence evaluation (such as mixed DNA stains or stains with low quantities of DNA).

Bayesian Networks

Preliminaries

Based on the elements of graph and probability theory, Bayesian networks can roughly be defined as a pictorial representation of the dependencies and influences (represented by arcs) among variables (represented by nodes) deemed to be relevant for a particular probabilistic inference problem. Since the early 1980s, Bayesian networks have gained increased acceptance in the field of expert system technology, which focuses on the study of knowledge bases associated to inference engines. Notably through their ability to coordinate principal probabilistic inference tasks, such as deduction (or prediction) and induction, Bayesian networks are now considered to be a general representation scheme for uncertainty in knowledge. Although graphical approaches to represent probabilistic information have already been discussed in the first half of the nineteenth century, it is now generally agreed that the seminal works of Judea Pearl in the 1980s have initiated the development of the formalism known today as Bayesian networks.

The name 'Bayesian networks' is among the most frequently encountered designations. According to the field of application, a variety of other terms – some with possible nuances in definitional details – may be encountered. Among these terms are 'Bayes nets,' 'Bayesian belief networks,' 'Bayesian expert systems,' 'graphical probabilistic networks,' 'probabilistic network models,' or 'causal networks.' For example, the term 'belief' in 'Bayesian belief networks' is sometimes emphasized

to point out that the probabilistic assignments used in a given model reflect degrees of personal belief of the individual who conducts a given probabilistic modeling and inference process. In yet other contexts, the notion of 'causality' is sometimes used. This stems from the fact that the links between the nodes of a Bayesian network can be interpreted as causal relationships, even though the definition of Bayesian networks does not refer to causality and there is no requirement that the links represent causal impact.

Definition and Properties

Bayesian networks are a combination of graph theory, which is used to provide a qualitative model structure, and probability theory, which is used to characterize the nature and strength of the relationships that reign within a model. More formally, a Bayesian network covers the following elements:

- A finite collection of random variables that are represented by nodes. Each of these nodes has a finite set of mutually exclusive states. In the context, these may also be called 'outcomes.'
- A set of directed edges that connect pairs of nodes.
- The set of variables and the set of directed edges are combined in such a way that a directed acyclic graph is obtained, that is, a graph where no loops are permitted.
- Node probability tables are associated with each variable of a network. The probability table of a variable A that receives entering edges from variables $B_1, \dots, B_n$ contains conditional probabilities $\Pr(A|B_1, \dots, B_n)$, whereas a variable A with no entering edges from other variables contains unconditional probabilities $\Pr(A)$. The term 'unconditional' refers here only to the absence of an explicit conditioning on other variables (nodes) in a network. Strictly speaking, a probability of the kind $\Pr(A)$ is also considered as conditional because there is always contextual information, habitually denoted by I , which is used when quantifying $\Pr(A)$. This implies that $\Pr(A)$ should be written more correctly as $\Pr(A|I)$, but I is often omitted to reduce notational burden.

The nodes of a Bayesian network represent propositional variables of interest, that is, very generally speaking, statements or assertions that such and such is the case. This may be an outcome or a state of nature. It is assumed that personal degrees of belief can be assigned to these states. Propositions are basic intellectual attributes formed by an individual during the course of a reasoning task. A proposition can be thought of as referring to states of affairs. Most often, the actual state may not be known with certainty. For example, there may be uncertainty about the truth or otherwise of the proposition according to which a crime stain has been left by the offender. Within a Bayesian network, such a proposition is conceptualized in terms of a node, whose states represent the truth and the falsity

of that proposition. The degree of belief maintained in each of these states is expressed numerically, that is, in terms of probabilities. These probabilities are organized in that node's probability table.

The mutually exclusive states of a variable are also referred to as the 'domain' of the variable. The domain of a variable may take one of different forms that will determine that variable's subtype. Examples include {red, green, blue} for a labeled variable, {T, F} for a Boolean variable (with 'T' and 'F' denoting 'true' and 'false,' respectively), $\{-2, 1, 4, 5, 7.34, 8\}$ for a numbered variable, and $\{]-\infty; 0], [0; 10], [10; 100]\}$ for an interval node. Note that the last node type is usable for specifying the intervals over which a continuous quantity can be implemented in a discrete form.

The arrows in a Bayesian network represent relationships that correspond to a property that an expert modeler assumes to hold within the context of an inference problem at hand. If a network is properly constructed, then a directed edge from a node A to a node B signifies that A has a direct influence on B . As an intuitively appealing way of presentation, the links between nodes are sometimes interpreted as 'causal relationships.' It is important to note, however, that the definition of Bayesian networks does not refer to causality and there is no requirement that the links represent causal impact. Broadly speaking, the links in a network represent probabilistic relevance relationships.

A distinctive feature of Bayesian networks is their incorporation of probability in terms of tables, associated with each node. This allows for interpreting the nature and the strengths of the relationships between a network's different graphical constituents. The node tables can accommodate probabilities from a variety of different sources. Among the most common sources are personal probabilities from human experts and (statistical) data from, for example, databases or the literature. Node probability tables can thus be considered as a means of interfacing a model to data. Besides, probability tables can also be completed by the use of mathematical expressions by exploiting various variable subtypes as described earlier.

An important property of Bayesian networks is the encoding of collections conditional independence assumptions and the representation of probability distributions. For the purpose of illustration, consider a distribution $\Pr$ defined on n discrete variables ordered arbitrarily as $A_1, A_2, \dots, A_n$. Using the product rule, the joint distribution $\Pr(A_1, A_2, \dots, A_n)$ can be decomposed as follows, also known as the 'chain rule':

$$\Pr(A_1, A_2, \dots, A_n) = \left[\prod_{i=2}^n \Pr(A_i | A_1, \dots, A_{i-1}) \right] \Pr(A_1)$$

A more economic representation of a joint probability distribution can be obtained if one is capable of specifying variables that are not 'sensitive' to all predecessors but only to a certain subset of those predecessors. Stated otherwise, a variable A_i may be independent of all other predecessors once a selected group of predecessors of A_i , called 'parents' (par) of A_i , is known. In such a case, the product of the above equation can be rewritten in a shorter form: $\Pr(A_i | \text{par}(A_i))$. Now, if the conditional independencies in a Bayesian network hold for the collection of variables $A_1, A_2, \dots, A_n$, then the Bayesian network provides a representation of the joint probability

distribution $\Pr(A_1, A_2, \dots, A_n)$ in terms of the product of all specified potentials, that is,

$$\Pr(A_1, A_2, \dots, A_n) = \prod_{i=1}^n \Pr(A_i | \text{par}(A_i))$$

where $\text{par}(A_i)$ represents the set of parental variables of A_i . The latter equation is called the 'chain rule for Bayesian networks' and formally defines what a Bayesian network means: a representation of the joint probability distribution for all the variables.

A key task operated by Bayesian network consists of the processing of newly acquired information; that is, calculating the conditional probabilities of the states of the nodes in the network given that the values of some of the nodes have been observed. It is customary to denote the latter as 'evidence variables' and the former as 'query variables.' Broadly speaking, the term 'evidence' can be interpreted as information that is available to a particular individual and that is thought to be incorporated into the system of beliefs maintained by that individual. In forensic contexts, such 'information' may consist of one or more propositions whose actual state becomes certain for the individual conducting the inference task (e.g., when a scientist decides that there is a 'match' between evidential and reference material). This would then provide the basis for reasoning about other propositions that have a bearing on an inference problem of interest. There may also be occasions in which 'information,' or 'evidence,' may be of a more technical nature, such as numerical data generated by an experimental procedure (e.g., a number of glass fragments collected on a suspect's clothing or, in the context of DNA evidence, detected alleles of genotypes). Such numerical data may directly qualify as input data that can be accommodated by a Bayesian network (e.g., by means of a numbered node). Evidence on a variable thus corresponds to a statement of the certainties of that variable's states. If it is known with certainty in which state a variable is, then the evidence is called 'hard' and the node is said to be 'instantiated.' Alternatively, an instantiated variable may also be referred to as an 'observed' variable. Generally, evidence that is not 'hard' is called 'soft.' One can also talk about evidence in terms of a function. For a variable with discrete states, for example, an evidence function that assigns a zero probability to all but one state may be said to provide hard evidence.

In Bayesian networks, evidence is processed according to Bayes' theorem. This represents one of the main points of interest for the study of Bayesian networks for probabilistic inference in forensic science. A convenient graphical illustration of this property amounts to a two-node network, involving the two binary variables H and E , in terms of the following representation: $H \rightarrow E$. A very common, general instance that can be represented in this way is the evaluation of a screening test where E refers to the result of the test (which may be either positive or negative) and H is the proposition about which one is uncertain. For example, one may be uncertain about whether or not a trace is human blood or whether or not an unknown powder contains something illegal. On observing that E holds, one seeks to calculate $\Pr(H|E, I)$, where I denotes additional contextual information. To apply Bayes' theorem for this task, that is, $\Pr(H|E) = \Pr(H, E) / \Pr(E)$, the following calculations are

needed (omitting I for shortness of notation): (i) $\Pr(H, E) = \Pr(H)\Pr(E|H)$ and (ii) $\Pr(E) = \Pr(E|H)\Pr(H) + \Pr(E|\bar{H})\Pr(\bar{H})$. Notice that calculation (ii) invokes the so-called extension of the conversation rule.

In the above computation, evidence on E is 'forwarded' to H against the direction of the arc that holds between these two nodes. It is important to note that within Bayesian networks, propagation is also possible along the direction of the arcs. To continue the example introduced above, propagation along the direction of the arc $H \rightarrow E$ means to calculate the probability of E given H , or $\Pr(E|H)$ for short. What happens during the passage from $\Pr(E)$ to $\Pr(E|H)$ can be seen in (ii). This relationship states that for assessing the uncertainty about E , uncertainty in relation to H needs to be accounted for. When H becomes 'known,' this means that $\Pr(H) = 1$ and $\Pr(\bar{H}) = 0$. Consequently, (ii) reduces to $\Pr(E|H)$, and this is just the respective value that has been specified in the conditional probability table of node E .

This description of probabilistic calculations that can be handled within Bayesian networks is informal and based solely on a local network fragment. Since the beginning of the development of Bayesian networks, researchers and practitioners have sought ways to automate these calculations, notably through computerized implementations. This was considered to be an essential step to be achieved if the approach is to be of use for real-world applications. A collection of algorithms are now available that allow calculations to be made in an efficient manner. These approaches have since then been implemented in academically and commercially available Bayesian network software.

Bayesian Networks for Probabilistic Inference in Forensic Science

'Early' Uses of Bayesian Networks for Particular Case Modeling

One of the first studies, in print, on Bayesian networks applied to forensic case settings was published in the late 1980s in the *Journal of the Forensic Science Society*. It focuses on a hypothetical murder scenario (see Figure 1) where the authors show how a network approach might be applied to cases involving several, possibly complicated, interrelated issues. They provide

Figure 1 Bayesian network for a hypothetical murder case. The nodes are defined as follows: A, 'X' committed the murder; B, 'Y' committed the murder; E, eyewitness evidence of a row between 'X,' 'Y' and the victim some time before the crime was committed; F, fibers from a jacket similar to one found in the possession of 'X' are found at the scene of the crime; H, 'Y' drives the car of 'X' regularly; T, 'Y' picks up fibers from jacket of 'X'. Reproduced from Aitken CGG and Gammernan AJ (1989) Probabilistic reasoning in evidential assessment. *Journal of the Forensic Science Society* 29: 303–316, with permission from Elsevier.

a detailed discussion on how (i) relevant propositions can be extracted from a scenario, (ii) relationships between propositions are represented qualitatively in terms of a directed graph, and (iii) subjective beliefs are incorporated as probabilities and used for inference.

Bayesian Networks for Generic Patterns of Inference

Instead of focusing on a particular scenario, as outlined in the previous section, it is also possible to pursue a modeling approach that aims at a standard analysis of recurrent patterns of inference concerning scientific evidence. This perspective concentrates on some more generic and fundamental issues that forensic scientists should account for if they seek to evaluate their evidence in the light of propositions that are of judicial interest. That is, the modeling concentrates on aspects of case settings that determine the general pattern of inference (e.g., the relevance of evidence), irrespective of situational detail. Figure 2(i) shows an example for such a Bayesian network, used for evaluating 'one-trace' cases involving transfer from the offender to the scene. It includes parameters such as

- the rarity of the compared characteristics among members of the relevant suspect population,
- the possibility that the stain would have been left by the suspect, even though he was innocent of the offense, or
- the relevance of the crime stain for the case (i.e., the probability that the stain has a true connection with the offender).

A more formal definition of the various nodes is given in Table 1.

Figure 2 Bayesian network fragments for (i) one-trace one-offender cases (involving transfer from the criminal to crime scene), (ii) the problem of laboratory error, (iii) results of a database search. Model (iv) shows a combination of the network fragments (i), (ii), and (iii). The definition of the nodes is as given in Table 1. Reproduced from Taroni F, Biedermann A, Garbolino P, and Aitken CGG (2004) A general approach to Bayesian networks for the interpretation of evidence. *Forensic Science International* 139: 5–16, with permission from Elsevier.

Table 1 Definition of the binary nodes used in the Bayesian networks shown in Figure 2

Node	Definition
H	The suspect is the offender
S	The crime stain came from the suspect
G	The crime stain came from the offender
M	The suspect's blood and the crime stain have matching
R	Reported match between suspect's profile and the profile of the crime stain
D	The other (N-1) profiles of the database do not match

Figure 2(ii) shows a more refined representation of a situation in which one seeks to draw an inference about S , the proposition according to which the suspect is the source of a crime stain. A particular aspect of this model is a distinction between (a) a true, but actually unobserved, correspondence between the profiles of the crime stain and a reference sample from the suspect (node M) and (b) an observed (or reported) correspondence by the scientists. This distinction allows the incorporation of a probability for a false positive. This situation, a false positive, occurs when a report states a correspondence when in fact the crime stain and the suspect have different profiles.

Figure 2(iii) is also amenable for an inference about the proposition M but extends to the additional item of information D that a certain number of profiles in a database were found to be different from that of the crime stain. This is a relevant supportive item of information that exerts distinct support for the proposition that the suspect is the source of the crime stain, in the same way as is learning about a match M between the profiles of the suspect and the crime stain.

It is important to mention that all three Bayesian networks, Figure 2(i)–(iii), have a probabilistic underpinning that agrees with published likelihood ratio formulae that seek to assess the probative value of DNA evidence in the respective situations. A further aspect worth mentioning is that these network fragments can also be logically combined so as to lead to the model shown in Figure 2(iv). This model allows for a joint evaluation of the various aspects considered in the separate local network fragments. This illustrates that Bayesian networks play an important role for coherent representation of complicated patterns of evidence. In particular, it is possible to address inference problems on a more local level first and then using the fragments thus constructed for reasoning on a problem of higher complexity. Above all, however, a model remains a probabilistic interpretation of a real phenomenon (or, more generally, an inference problem) that is constructed at a given level of acceptable approximation. It does not amount to a claim of ‘true model.’

Advanced Bayesian Network Approaches for Assessing DNA Evidence

Representation of genotypes

In the previous sections, a single discrete node was generally used for representing the outcomes of DNA analyses (e.g., the proposition according to which the crime stain and the suspect’s blood ‘correspond’ with respect to their DNA profile). In the simplest case, this perspective amounts to a two-node network fragment in which knowledge about the state of an observational variable, such as E (e.g., short for ‘DNA match’), is used for drawing an inference about propositions according to which the ‘matching’ suspect is (is not) the source of the crime stain. If the latter propositions are represented by H , the Bayesian network would take the structure $H \rightarrow E$.

Besides these formative and coarse modeling approaches, considerable additional research has been devoted to the application of Bayesian networks to inference problems involving the results of DNA analyses. An important direction of research in that area focuses on basic representational schemes, usable as repeatable modules in analogous situations. These

Figure 3 Representation of an individual’s genotype as the minimum (*gtmin*) and maximum (*gtmax*) of the two parental gene nodes *pg* and *mg*, inherited via the paternal and maternal line, respectively. Reproduced from Dawid AP, Mortera J, and Vicard P (2007) Object-oriented Bayesian networks for complex forensic DNA profiling problems. *Forensic Science International* 169(2–3): 195–205, with permission from Elsevier.

submodels are more fine-grained network fragments focusing on individual genes, rather than on full genotype representations. An example of this is a network with the converging connection $mg \rightarrow gt \leftarrow pg$, where node gt represents a genotype that is modeled as a logical combination of the alleles inherited from the mother and father. These parentally inherited genes are represented by the nodes mg and pg , to be read ‘maternal gene’ and ‘paternal gene’, respectively. A gene A , for instance, can take one of several different forms, also called alleles. Suppose there are n alleles at gene A . These alleles may be denoted $A_1, A_2, \dots, A_n$ at a given locus. In the Bayesian network $mg \rightarrow gt \leftarrow pg$, the states A_1, A_2 , and A_x are assumed for nodes mg and pg . The third state, A_x , accounts for all unobserved alleles $A_3, \dots, A_n$. The possible states of the genotype node gt may then be defined as $A_1A_1, A_1A_2, A_1A_x, A_2A_2, A_2A_x$, and A_xA_x , which are all the logical combinations of pairs of alleles.

For a more general ready-to-use representation, one might want to specify, for each parental gene pg and mg , the full repertory of alleles at a given locus. However, this may lead to a rapid increase in the size of the probability table for the node gt . This can be avoided by separating the node gt into two distinct nodes *gtmin* and *gtmax*, as shown in Figure 3. These two nodes represent, respectively, the minimum and the maximum of the two parental gene nodes pg and mg .

Relatedness testing

The application of the more detailed modeling approach for genotypes, outlined in the previous section, can be illustrated in the context of a scenario of disputed paternity. Consider that a certain male, denoted as the putative father pf , is supposed to be the father of a certain child c . DNA profiles are available on the mother m , the putative father pf , and the child c . The entity of interest is the likelihood ratio for the proposition that the putative father pf is the true father tf , noted $tf=pf?$, given knowledge about the child’s genotype cgt and the mother’s genotype mgt . The paternity pedigree corresponding to this inference problem is shown in Figure 4(i). A representation of this disputed paternity case in terms of a Bayesian network is shown in Figure 4(ii). There would be a Bayesian network of this kind for each genetic marker that has been analyzed. These networks can be analyzed separately and the resulting likelihood ratios combined subsequently. An alternative way of proceeding consists of combining the single-locus networks within a single ‘top-level’ network, in the context also called ‘supernetwork.’

The Bayesian network depicted in Figure 4(ii) allows one to obtain the same results as with classic arithmetic calculus of Essen-Möller under the Hardy-Weinberg assumption of

Figure 4 Different representations of a case of disputed paternity: (i) paternity pedigree (with squares representing males and circles females, pf denoting the putative father, tf denoting the true father, m denoting the mother and c denoting the child) and (ii) a Bayesian network. For the Bayesian network, $tfpg$, $tfmg$, mpg , and mmg denote the paternal p and maternal m (in second place) genes of the true father tf and the mother m (in first place); cpg and cmg denote the child's paternal and maternal genes, respectively; $pfpg$ and $pfmg$ denote the putative father's paternal and maternal genes, respectively; $pfgt$, mgt , and cgt denote the genotypes of the putative father, the mother and the child, respectively, and $tf=pf?$ takes two values in answer: 'yes' or 'no' as to whether the true father is the putative father. Reproduced from Dawid AP, Mortera J, Pascali VL, and van Boxel D (2002) Probabilistic expert systems for forensic inference from genetic markers. *Scandinavian Journal of Statistics* 29: 577–595, with permission from Wiley.

Figure 5 Bayesian network for evaluating DNA typing results in a one-stain scenario when the alternative proposition at the source level is that the suspect's brother left the stain. The nodes B , tgt , and sgt are instantiated, meaning that the suspect is assumed to have a brother and that information is available about the genotype of the suspect and the crime stain. Node F is the source node, with two states, F , the suspect is the source of the crime stain, $\bar{F}$, a brother of the suspect is the source of the crime stain. Node B has two states: B , the suspect has a brother, and $\bar{B}$, the suspect does not have a brother. Nodes fpg , fmg , mpg , mmg , spg , smg , bpg , bmg , tpg , and tmg are gene nodes, with three states, states A_1 , A_2 , and A_x . Nodes fgt , mgt , sgt , bgt , and tgt are genotypic nodes. Note that f denotes father, p paternal, m mother (if in first place) or maternal (if in second place), s suspect, b brother and t trace (if in first place). Instantiated nodes are shown with a bold border. Reproduced from Taroni F, Aitken CGG, Garbolino P, and Biedermann A (2006) *Bayesian Networks and Probabilistic Inference in Forensic Science*. Chichester: Wiley, with permission from Wiley.

independence. One might thus be tempted to conclude that there is no real gain by working with Bayesian networks, as there is indeed no need to develop new methods for problems that can be solved by simple algebra. However, the very aim of proposing the network shown in [Figure 4\(ii\)](#) is different. It provides a solid basis for evaluating DNA evidence and serves as a starting point for approaching more complex problems that accompany the evaluation of forensic DNA evidence, such as missing data (i.e., when profiling data of some individuals are unavailable), additional data (e.g., from a related person, if available), or mutation.

Inference of source for crime stains

Besides relatedness testing, the network approach to inference based on typing results for genetic markers, as presented in the previous sections, is also very helpful for addressing evaluative questions about crime stains. [Figure 5](#) illustrates this in terms of a full numerically specified example in which the profile of a crime stain is assumed to correspond to the profile of a suspect. The analysis focuses on a hypothetical marker with alleles A_1 , A_2 , and A_x , as defined previously. The population proportions for A_1 and A_2 have been set to 0.05. In [Figure 5](#), the node F displays the posterior probability that the suspect is the source of a crime stain (which is found to have the profile A_1A_2), given that the suspect has the same DNA profile as the crime stain, whereas the alternative proposition is that a brother of the suspect – unavailable for testing – is the source of the crime stain. Besides, this network could also readily be extended to incorporate the possibility that a random member of the general population is the source of the crime stain.

Conclusions

Despite the various compelling capacities of the Bayesian network formalism, the manual model construction may often be a painstaking process, in particular, for larger applications. As a means to overcome such difficulties, Bayesian networks have been extended to ‘object-oriented Bayesian networks.’ The idea behind this approach is to define generic ‘classes’ of networks, particular nodes of which (so-called ‘instances’) can be used, as required, in place of nodes in other networks. The object-oriented Bayesian network language thereby allows one to describe inference problems in terms of interrelated objects. This currently represents a major direction of research in Bayesian networks for inference from genetic markers. This approach is also helpful for combining typing results from several genetic markers.

More generally, Bayesian networks represent a powerful graphical approach for evidence evaluation (also other than DNA) in judicial contexts. Compared to most previously developed graphical methods, the use of Bayesian networks offers

the additional advantage of incorporating probability theory as a coherent measure of uncertainty. Moreover, computerized systems currently exist that can perform calculations over a number of variables with varying dependency structure. More recent developments, in particular, the extension to object orientation, have further increased the capacity of Bayesian networks to deal with the level of complication that is associated with real-case settings involving DNA evidence. Bayesian networks thus represent a complementary contribution to the body of analytical techniques that are needed to approach inference problems in accordance with probability theory, both conceptually and practically.

Glossary

AMOVA A method that measures the genetic distances between subpopulations (e.g., of a metapopulation); this can be done frequency-based (F_{st} statistics) or with taking the molecular relationship between alleles into account (Φ_{st} statistics); results can be illustrated in an MDS plot.

Discrimination capacity (DC) The number of haplotypes in a sample which can be separated by a certain number of polymorphic sites, for example, STRs or SNPs.

Haplogroup A set of mtDNA or Y chromosomal haplotypes that is defined by nonrecurrent, slowly mutating markers such as SNPs.

Haplotype The combination of allelic states of a set of polymorphic markers lying on the same DNA molecule, for example, the Y chromosome or the mitochondrial DNA.

Metapopulation A group of populations connected by ancestry and migration.

Quasi-median networks (QMN) Graphical representations of haplotypic data, permitting visual assessment of the haplotypes based on their evolutionary relationships to each other.

Y-STR A DNA sequence containing a number (usually <50) of tandemly repeated short (2–6 bp) sequences, such as (GATA)_n. Often polymorphic and also known as microsatellites.

Introduction to the Y Chromosome and Mitochondrial DNA Database Projects

Lineage markers have special fields of application in forensic genetics. Y chromosome analysis is very helpful in cases where there is an excess of DNA from a female victim and only a low proportion from a male perpetrator. Typical examples include sexual assault without ejaculation, sexual assault by an azoospermic (vasectomized) male, male DNA under the fingernails of a female victim, male 'touch' DNA on the skin, and the clothing or belongings of a female victim. MtDNA analysis is of importance for the analyses of low target number DNA, namely from unidentified (typically skeletonized) remains, hair shafts without roots, or very old specimen where only heavily degraded DNA is available. The unusual non-recombinant mode of inheritance of Y and mtDNA weakens the statistical weight of a match between individual samples but makes the method efficient for the reconstruction of paternal or maternal relationship, for example, in mass disaster investigations. In practice, most laboratories conduct DNA analysis according to a workflow which characterizes the sample DNA extract with regard to quantity, degradation state, or sex ratio prior to any STR analysis, allowing the analyst to make the most informed decision on the best method to proceed. This workflow produces a lot of DNA profiles from mtDNA and Y chromosomal STRs, which do not exclude but match a person as a donor of a trace. Because statistical interpretation is obligate in forensic reporting for all kinds of DNA sequences, including linear markers, the probability that a particular genotype might occur at random in a population must be calculated and expressed in numerical terms. This inevitably requires very large databases to retrieve frequencies of the haploid profile detected in the trace. Owing to intense international collaboration within the forensic community, these databases are available, accessible via Internet, and constructed to

comply with the quality standards required for forensic reference data. The Y chromosome haplotype reference database (YHRD) was established in 1997 and went online in 2000. The database currently contains 97 575 haplotypes from 739 populations (release 37 built on 21 June 2011). About 37% of these are typed for the maximum of 17 loci as included in the AmpFSTR® Yfiler™ PCR Amplification Kit (Figure 1). The YHRD is hosted at the Department of Forensic Genetics, Institute of Legal Medicine Berlin, Charité – Universitätsmedizin Berlin in Germany. The EDNAP Mitochondrial DNA Population Database (EMPOP) was established in 1999 and went online in 2006. The database currently contains 14 847 haplotypes (release 5 built on 5 July 2011, Figure 2). EMPop is hosted at the Institute of Legal Medicine, Innsbruck Medical University in Innsbruck, Austria.

What is the *raison d'être* for such voluminous repositories which connect local databases to a metadatabase? The answer lies in the aforementioned nonrecombinant nature of Y chromosomes and mtDNA, which represent, in effect, a single locus. The 'product rule' used to obtain frequency estimates for unlinked autosomal alleles cannot be applied to estimate the population frequency of a certain combination of fully linked alleles (haplotype). These frequencies need to be calculated and reported on the basis of the number of observation (counts) in databases, which are representative for the population(s) of interest. Frequency estimates of a particulate haplotype thus crucially depend on the size and the content of the reference database used. To assess the representativeness of such databases, the extent of structure among populations also needs to be considered. This is particularly important for markers on the Y and mtDNA because of its haploid mode of inheritance, the reduced effective population size of the Y chromosome, and socially instituted practices as patri- or matrilocality makes them more sensitive to genetic drift than the autosomes and generates rather high between-population

Figure 1 YHRD growth 2000–11.

Figure 2 EMPPOP growth 2006–11.

diversities. This more pronounced stratification has important consequences for the sampling scheme. The database representation and the reporting are explained in the following sections.

Haplotype Sampling

Essential for the YHRD and the EMPOP projects is the collaborative character relying on the engagement of individual laboratories to make their data accessible and comparable via a common Internet platform and to agree on a high standard of data quality. The decentralized sampling strategy implies that each submitting group has to ascertain the sample population. This ascertainment includes informed consent documentation, measures to avoid sampling of close relatives or probands of nonlocal origin, and proper naming of the sample. Sample numbers depend on the size of the investigated population. Urban and cosmopolitan population studies should involve at least 200 individuals, whereas regional data sets should contain a minimum of 100 samples. Exceptions are valid for extremely small population sizes. Requested is also the publication of a manuscript that describes in detail the population(s) submitted to EMPOP or YHRD and contains the original data set. This manuscript is linked via an accession number to the respective database where the population sample can be searched. The names of the population samples chosen by the submitters need to follow a ternary code to define a minimum of causal relationship: region and country (ethnic/linguistic group). If sample populations are properly described, they can be merged into so-called metapopulations (MP). This means that geographically widespread populations that share a common genetic ancestry and are connected by migration can be joined to metapopulations. For example, Turks, Kalmyks (Russia), and Khalks (Mongolia) belong to the Altaic-speaking metapopulation; US American, Australian, and South African Europeans, as well as French, Spanish, or Irish, belong to the European MP; or Han, Hui, and She belong to the Sino-Tibetan MP. The extent of homogeneity within a metapopulation and the distance to others can be measured using the AMOVA algorithm by calculating genetic distances expressed by F_{st} or R_{st} values. It has been shown for an earlier edition of the YHRD with about 41 000 individuals that the chosen metapopulation classification is supported by the deeply structured haplotype data deposited in the database. Both databases supply inventories of included populations that serve as guidance for the assignment of the relevant termini. However, the geographical or linguistic classification is not the only way to represent the clustered structure of Y chromosomal and mtDNA types. There is also a phylogenetic classification possible, which is based on a monophyletic, hierarchical tree defined by unique event (nonrecurrent) polymorphisms or SNPs. Each branch of the tree (haplogroup) is defined by at least one SNP. All Y chromosomes or mtDNA molecules sharing a mutation are related by descent, until a further mutation splits the branch. Haplotypes within a haplogroup may be highly similar or even 'identical by descent.' Thus, the haplogroup can be used as a criterion to substructure the database according to the phylogenetic descent of samples. Many haplogroups can be equated

with events in human prehistory and show a geographical pattern. To accommodate the phylogenetic classification scheme, the YHRD database is continuously extended for binary Y-SNP polymorphisms and a grouping of Y-STR haplotypes according to haplogroups thus becomes feasible. Currently, 7168 Y-STR haplotypes (7.3%) have an experimentally determined haplogroup designation. The haplogroup affiliation of an mtDNA sequence is already present in the reported haplotype that is generated for forensic discrimination. Owing to the high degree of homoplasmy in the mtDNA, CR haplogroup determination can be supported by coding region information (SNPs), but in the majority of samples the rough haplogroup status can be derived from control region profiles.

The Quality Assessment Scheme of YHRD and EMPOP

The quality assessment scheme is of utmost importance for the court acceptance of the reference data and the calculations adapted from these data. All institutions contributing haplotypes to the databases have to pass an obligate review to assess the quality of their data. For first submitters to YHRD also a QC test is mandatory, which includes five blind samples that have to be correctly typed for the submitted data set. The QC results will be evaluated and certified by the YHRD curatorial board. Submitted population data for both YHRD and EMPOP will be reviewed to find (1) typographical errors, (2) mistaken nomenclature, and (3) systematic deviations to the core haplotype distributions of the metapopulation or haplogroup. Once the lab has passed the QC and the data are evaluated, the lab receives an accession number for each submitted population sample. This accession number has to be included in the article, which will appear in one of the forensic journals (e.g., *For Sci International: Genetics*, *Int J Legal Med*, *Legal Med*) in the online rubric 'Announcement of population data.' The editors of the forensic journals closely cooperate with the database curatorial boards and have issued guidelines for the publication of population data, which have to be followed by submitting authors.

The past decade saw significant changes in how mtDNA has been investigated in the laboratory and how sequences are aligned and searched. The main motivation was a high-profile discussion on the low quality of published mtDNA data sets and an unacceptable high error rate in the early 2000s. In its first 7 years, the EMPOP project (1999–2006) primarily aimed at the identification of the sources of error in an in-depth manner and, as a consequence, laboratory protocols, documentation formats, and database logistics were adapted accordingly. Since its first release, EMPOP has not only been a resource of high quality curated mtDNA data but also included quality control mechanisms to alert the user when ambiguous data were applied. A robust method for detecting idiosyncrasies in mtDNA data that are available via the EMPOP website is the application of quasi-median networks (QMN). These essentially serve as graphical representations of tabular data, permitting visual assessment of the haplotypes based on their evolutionary relationships to each other (Figure 3). Since mtDNA data are characterized by a high degree of homoplasmy and recurrent mutations that both make QMNs complex,

Figure 3 Depiction of four quasi-median network torsos, HVS-I (16024–16400, filtered with hotspot_EMPOPspeedyWE). (a) Etalon torso, 202 west Eurasian haplotypes of forensic quality; (b) the addition of 31 west Eurasian high-quality sequences to the etalon has only minor effects on the display of the torso; (c) the addition of 29 sequences from a Darginian data set to the etalon increases the complexity of the torso by the introduction of 13 new quasi-medians (black dots), which indicate the presence of unobserved variation. Affected polymorphisms are transitions at 16280, 16281, and 16384, and a transversion at 16391 that all turned out as phantom mutations. (d) Removal of the phantom mutations from the data in (c) results in an inconspicuous torso.

specific filtering of mutations is necessary before a QMN can be calculated and drawn. The networks of reduced and condensed haplotypes are simple when the quality of data is high (Figure 3(a), (b), (d)). Quasi-medians represent virtual haplotypes that are not included in the sample set but required to link the sequences in the QMN. Therefore, the number of quasi-medians is augmenting with increasing phylogenetic distance of the samples, such as when, for example, mtDNA sequences from Europe (superhaplogroup N) and Africa (superhaplogroup L) are merged in one set. Errors in sequence data lead to a similar picture, as has been shown by Hans-Jürgen Bandelt and coauthors in the late 1990s. They usually lead to an increase in quasi-medians and thus indicate that review of the sequence raw data is necessary (Figure 3(c)). The generation of QMNs is supported by EMPOP under the 'tools' section, a more detailed description of the process and examples can be found there.

The Tool Boxes of YHRD and EMPOP

YHRD

The YHRD can be searched for all single alleles and all allele combinations in a continuously growing and regularly updated data set. Because new releases replace the previous ones, the release number and date are an important part of the 'Search result' document. The database supports the most frequently used haplotype formats (e.g., minimal

haplotype=minHt, SWGDAM, PowerplexY or Yfiler haplotype) for which differently sized databases exist. The discrimination indices in four population sets for typical haplotype formats are depicted in Figure 4.

At each position of the search mask, the respective allele must be entered. To facilitate the search, the scroll-down menu shows all alleles that have been observed in the database at the respective locus. Irregularly spaced STR alleles are named according to the ISFG recommendations. The database has a structure that can be adapted to the needs of the user allowing searches in the whole database or in subsets defined by the metapopulation, the nationality, or the haplogroup of the sampled chromosomes. Currently, Y-STR profiles can be searched within 7 continental sets, 34 hierarchically arranged metapopulations, 108 countries, and 118 haplogroups (release 37 from June 21, 2011, see Figures 5 and 6). A query returns a printable document which includes the absolute number of matches in the tab-selected database type (MPs, continents, haplogroups) and the relative frequency value including the confidence interval limits calculated according to the exact Clopper–Pearson method. Though very simple and easily defensible, this approach known as the counting method has limitations due to the reduced size of the database and sampling effects especially in poorly sampled populations. By clicking the tab 'Frequency surveying estimates,' the result page presents frequencies calculated by a Bayesian extrapolation method. This method – which is an alternative option to calculate frequencies for rare or unobserved haplotypes by counting – is applicable only for haplotypes with ≥ 9 STR and for 11 well-saturated reference databases representing populations of European, Asian, and African ancestry. The frequency of a haplotype in question is represented as a beta-type posterior distribution with mean (mean likelihood estimate) and mode points (maximum likelihood estimates). This posterior distribution is obtained by extrapolation from the structure and frequency of all other haplotypes in the relevant ancestral group (MP). We recommend the mean value as a robust estimator of the frequency of a rare haplotype. If the counting method is used in case of unobserved haplotypes, a truthful estimate can be retrieved either by adding the unobserved haplotype to the database ($1/(n+1)$) or by using the upper confidence interval limit (CIL) which is reported at the result page in case of zero observations.

Scrolling the result page further down shows a scalable and movable map on the basis of the Google Maps software, with the relative proportion of matches shown in red/blue for each geocoded sampling location. There are several tools to customize the map. Clicking a geoposition in the map opens a window with essential information on the population sample(s), including name, assigned continent, ethnicity, and metapopulation, as well as the frequency of the searched haplotype at this position. Further down a table with all matched and one-step neighboring haplotypes is shown. The population summary beneath these tables finally presents the matches per single population sample ordered (in default mode) by absolute numbers. Clicking on the population name opens a window with essential information on the contributor(s) or submitting institutions. The accession numbers for this population can be clicked in this window and guide the user directly to the contributor's page presenting full reference to the sample and links to the publication(s).

Figure 4 Discrimination capacity (DC) in different YHRD population sets (release 37).

For the interpretation of Y-STR evidence in cases of mixture, a tool has been implemented in the YHRD. This program allows calculating likelihood ratios for varying numbers of known and unknown contributors. The database delivers population-dependent frequencies of the haplotype profiles detected in the trace.

Furthermore, a tool to assess the extent of population substructure the AMOVA algorithm has been programmed and implemented in the YHRD database. Analysis of molecular variance (AMOVA) is a method for analyzing population variation using molecular data, for example, Y-STR haplotypes. The online tool accepts Excel files and creates entry files from it. As much as nine reference populations or population sets from the YHRD plus the test population sample can be added to the AMOVA analysis. The calculation returns a *.csv table with pairwise F_{st} or Φ_{st} plus p values as a significance test (10 000 permutations). In addition, an MDS plot is generated to illustrate the genetic distance between the analyzed populations graphically. The program lists the references for the selected population studies which facilitates the correct citation. A detailed description of the YHRD tools is published in the manual 'YHRD 3.0, Directions for use,' which can be downloaded from the website.

EMPOP

EMPOP allows for sequence searches in two different formats, as rCRS-coded haplotype that is the common reporting format of mtDNA variation and as (FASTA-like) nucleotide sequence string that represents the output format of a raw data derived consensus sequence. Alignment and annotation of rCRS-coded haplotypes are known to be ambiguous, which means that there is more than one possible way of calling (mainly due to insertion/deletion events that can be differently aligned relative to the rCRS). To avoid that such haplotypes are mistakenly missed in a database search, the query and database sequences are turned into strings of nucleotides that are then compared (SAM) and presented relative to the rCRS again in the output. This solution guarantees that database sequences are not missed due to different alignment, which is very important for retrieving objective database search results. EMPop is so far the only freely available database that includes this feature.

Haplotypes in EMPop are defined by their sequence range. The query engine allows for any user-defined ranges to be searched complying with the variety of sequencing results from pristine to degraded mtDNA. In an attempt to offer highest discrimination, power haplotypes covering the entire

Figure 8 Representation of 'Forensic' and 'Literature data' in EMPOP.

Figure 9 Representation of continents in EMPOP (r. 5).

control region are primarily loaded onto EMPOP. However, the majority of existing sequences are present in the earlier targeted HVS-I and HVS-II formats, which are also included in the database to increase the generally low representation of mtDNA haplotypes (Figure 7).

'Forensic data' in EMPOP refer to haplotypes that are represented by and permanently linked to high-quality raw data. This allows the curator to check questionable positions any time. 'Literature data' undergo the same scrutiny of quality control; however, raw lane data are either absent or do not meet the required forensic standards (i.e., sequence quality). Nevertheless, 'literature data' can also be used for determining the rarity of a haplotype in a forensic setting (Figure 8).

The SAM addresses the issue of point heteroplasmy by differentiating literal and pattern search modes. The former restricts full matches to the presence of haplotypes with completely identical heteroplasmic positions, that is, 152Y only matches 152Y and not 152C. The latter treats mixture designations as matches with their components, that is, 152Y matches T152 and 152C and vice versa. The search engine also allows length heteroplasmy at the notorious C-tracts around positions 16189, 310, and 573 to be disregarded, which makes frequency estimates more conservative. Query haplotypes are reported by the counting method and can be specifically searched according to geographic (Figure 9) and metapopulation categories. Frequency values are calculated based on the number of observations indicating lower and upper bound confidence intervals (according to the Wilson method).

Unobserved haplotypes are added to the database according to the $(1/n+1)$ method to achieve a conservative frequency estimate.

EMPOP offers a tool section that currently holds software to aid the quality check of a (new) data set (EMP TOOL). These haplotypes can be sorted according to different criteria, while plausibility and formal checks are performed.

Furthermore, online database projects with forensic relevance comprise the Chromosome X database presenting X-STR frequencies, the ENFSI STR database for common autosomal STRs, and a national US database for Y-STRs.

History of the International Society for Forensic Genetics – ISFG

N Morling, University of Copenhagen, Copenhagen, Denmark

© 2013 Elsevier Ltd. All rights reserved.

The International Society for Forensic Genetics – ISFG – was founded on 24 June 1968 at a meeting at the University of Mainz, Germany, by a group of dedicated blood group serologists (**Table 1**) under the name ‘Gesellschaft für forensische Blutgruppenkunde’ (Society for Forensic Haemogenetics). Thus, the ISFG is a German, nonprofit society that was registered on 31 July 1968 at the District Court, Mainz, Germany (registration no. 1006).

The initial aim of the society was to establish a scientific platform for the study of genetic markers in human blood for use in forensic genetics. The number of both German-speaking and other international members increased rapidly and, in 1989, the Society was made an international society (‘International Society for Forensic Haemogenetics’) with German and English as the official languages. Since 1993, all presentations at the ISFG congresses have been given in English. In 1991, the name of the Society was changed to ‘International Society for Forensic Genetics,’ reflecting that almost all kinds of tissues can be typed successfully with DNA methods. The statutes of the ISFG from 2011 are shown in **Table 2**.

Executive Board of the ISFG

The board of the ISFG has five members (**Table 3**).

The ISFG presidents are listed in **Table 4**. Lists of other board members are found at <http://www.isfg.org>.

Honorary Members

All activities of the ISFG are unpaid and nonprofit. Many members have made very valuable contributions to the society. The general assemblies have appointed a number of honorary members (**Table 5**).

Membership

In 2001, the ISFG had more than 1100 individual members from more than 50 countries. The members typically work with forensic genetics in academic institutions (universities, etc.), criminal justice, and police organizations, as well as private companies. The members’ expertise includes molecular and population genetics, blood group serology, biostatistics, criminal law, medical ethics, etc. Applicants need recommendations from two members of the ISFG. The membership fee (in 2011: EUR 60.00 per year) includes reduction of the registration fee at the biannual congresses and a subscription (print and online version) to the scientific journal ‘Forensic Science International: Genetics’ that is affiliated with the ISFG.

Commercial companies can become corporate members to express their support for the aims of the society.

The Biannual ISFG Congresses

The most important activity of the ISFG is the international congresses that are being held biannually. The location and the president of the congress are decided by the general assembly of the ISFG. The 2007 and 2009 ISFG congresses were attended by more than 600 participants (**Table 6**).

Proceedings of the ISFG Congresses

Since 1997, the proceedings of the biannual ISFG congresses have been published in Progress in Forensic Genetics, Elsevier. Since 2007, the proceedings are freely available through Forensic Science International: Genetics Supplement Series (<http://www.fsigeneticssup.com>). In the period 1985–95, the proceedings were published in Advances in Forensic Haemogenetics by Springer.

Scientific ISFG Prizes

The board of the ISFG can award scientific prizes. The scientific prize is given at the biannual ISFG congress. The prize winner is encouraged to give a presentation of the scientific work at the following ISFG congress (**Table 7**).

The Language-Based Working Parties

The ISFG has the following language-based working groups: Chinese, English, French, German, Italian, and Spanish–Portuguese. The working groups typically treat items of regional or national interest. Some of the working groups also offer quality control and proficiency testing exercises (<http://www.isfg.org>, <http://www.rtw-eswg.forensic.ku.dk> and <http://www.gep-isfg.org/ISFG/English/portada.php>).

The DNA Commission

Since 1989, the board of the ISFG together with invited scientists has established various ad hoc working groups called

Table 2 Statutes of the ISFG 2011 – translation from German into English**§ 1 – Name and Place of Registration**

The International Society for Forensic Genetics is incorporated with place of registration at Mainz.

§ 2 – Aims

- (1) The society aims to promote scientific knowledge in the field of genetic markers in human blood. This is to be accomplished by scientific meetings of the society, meetings of regional working parties, and by scientific publications.
- (2) The society strives for cooperation with other scientific bodies. The society especially is always ready to assist public inquiries.

§ 3 – General Usefulness

- (1) The society's sole scientific purpose is given in the sense of "beneficiary tax purpose" of the German Tax Code (Abgabenordnung).
- (2) The society does by no means pursue an economical purpose. The funds of the society may only be applied for appropriate statutory purposes. The members receive no fees in their capacity as members and also no other allowances out of the funds of the society.
- (3) No person may be supported in a way inappropriate to the purposes of the society or benefit of inappropriate allowances.

§ 4 – Membership

- (1) Any academic graduate, dealing scientifically with genetic markers in human blood, can apply for full membership.
- (2) Corporate members (e.g. commercial companies) can be enrolled as members, but they do not have the right to vote.
- (3) Applications for membership must be made to the Executive Committee of the society together with references from two full members. Admission to the society is subject to the decision of the Executive Committee.
- (4) Membership is terminated by written notice of withdrawal, death or by disqualification. Notice of withdrawal is given by registered letter to the Executive Committee.
- (5) Scientists, whose contributions are of great importance in respect to haemogenetics and any other persons who especially deserve acknowledgement by the society, can be nominated as honorary members. This is subject to the decision of the General Assembly.
- (6) The membership may not be used for advertising purposes.
- (7) Any scientifically interested person is able to become an extraordinary member without the right of voting, as far as these are not listed up in point (1).

§ 5 – Executive Committee

- (1) The Executive Committee consists of the President, the Vice-president, the Representative for all Working Parties, the Secretary and the Treasurer.
- (2) The General Assembly elects the Executive Committee by secret ballot and by a simple majority of votes from the membership. The Treasurer and the Secretary are elected for four years consecutively, the other members for the Executive Committee for two years. If the President is re-elected the Vicepresident is also re-elected automatically for another two years. Only one reelection is permitted.
- (3) The newly elected Executive Committee takes over its official function on the first January following the election; until then the former Executive Committee remains in office.
- (4) The Executive Committee is still authorized to pass resolutions, even if one member should withdraw prematurely. The required by-election then takes place at the next General Assembly.
- (5) The Executive Committee may invite guests for the Board Meeting.

§ 6 – Authorization for Representation

Two members of the Executive Committee represent the society in the sense of § 26 BGB (German Civil Code).

§ 7 – General Assembly

The General Assembly pays particular attention to the following:

- Receiving of the annual report, also the annual report of the treasurer,
 - Election of members of the Executive Committee,
 - Relief of the members of the Executive Committee,
 - Appointment of honorary members,
 - Establishment of time and place of scientific conventions,
 - Decision of regulations if necessary,
 - Decision of alterations of statutes and regulations,
 - Decision of dissolution of the society.
- (2) The General Assembly passes a resolution with a simple majority as long as the statutes do not read differently.
 - (3) As a rule, the General Assembly takes place on the occasion of a scientific convention. Therefore, the Executive Committee must take known, in writing, appointed time of the convention 6 weeks in advance. A topic which does not belong or appear on the agenda can be introduced without resolution, providing 3/4 of the members are in favour of its acceptance.
 - (4) A special General Assembly can be called by the Executive Committee. It must be called for by at least 1/4 of the members who have submitted reasons to the Executive Committee.
 - (5) Upon the decision of the Executive Committee or upon the request of at least 100 ordinary members or upon the decision of 2/3 of the members present at the General Assembly a vote concerning business affairs may be carried out by letter.

§ 8 – Scientific Conferences

- (1) At least every two years a scientific conference is held.
- (2) Each member may bring forward proposals concerning the program. The proposals must be received by the Executive Committee at least 4 months in advance. It is up to the Executive Committee to decide the scientific subject of the papers and to choose the speakers.
- (3) The International Society for Forensic Genetics can distribute every 2 years, on the occasion of the scientific congresses, the "Scientific Prize of the International Society for Forensic Genetics", according to special statutes.

(Continued)

Table 2 (Continued)

§ 9 – Membership Subscriptions, Auditor, Business Year

- (1) A yearly membership subscription is raised, which becomes due at the beginning of the calendar year and the amount of which is fixed by the General Assembly. Changes in the subscription fees become valid at the beginning of the following calendar year.
- (2) Honorary members are not eligible to subscription fees. For corporate members the subscription fees agreed upon are the minimum and are agreed on an individual basis by self-assessment.
- (3) At the end of a business year the cash account of the society is checked by two auditors elected from the General Assembly. The latter report to the General Assembly.
- (4) The Business year is identical with the calendar year.

§ 10 – Working parties - Committees - Commissions

- (1) Working parties function for the exchange of experience.
- (2) The General Assembly can conclude the formation of working parties, committees and commissions.

§ 11 – Alterations of the Statutes

- (1) An application for alteration of the statutes, duly signed by at least 1/5th of the members, must be addressed to the President together with reasons three months before the General Assembly.
- (2) The Executive Committee is also entitled to propose alterations of the statutes with reasons to the General Assembly, the subject of which must be made known to the members together with the invitation to the General Assembly.
- (3) Alterations of the statutes are concluded by the General Assembly in accordance with § 33 BGB (German Civil Code) with a 3/4th majority of the present members. An alteration of the aims of the society is only possible with the agreement of all members.

§ 12 – Dissolution of the Society

- (1) The dissolution of the society can only be considered after the application of the least 2/3rd of the members has been brought before the Executive Committee within three months before the General Assembly takes place.

For the conclusion to dissolve the society a 3/4th majority of the present members is required.

- (2) When the society is dissolved, its property falls to the “Deutsche Forschungsgemeinschaft”, who will use it immediately for general utility purposes. The agreement of the relevant revenue office must be obtained beforehand.

The European DNA Profiling Group

The EDNAP group was established in October 1988 in London at a meeting of forensic genetic scientists from European countries. The initial purpose of EDNAP was to harmonize DNA technologies for crime case investigations so that DNA results could be exchanged across the borders in Europe. In 1991, EDNAP was accepted as a working group of the ISFG. Approximately 20 European laboratories are members of EDNAP. The EDNAP group collaborates closely with the DNA Working Group of the European Network of Forensic Science Institutes. The two groups usually organize common meetings twice a year. EDNAP organizes exercises to explore the possibility of standardization of new forensic genetic methods. The results of the exercises are published and made available on the ISFG website (see <http://www.isfg.org>).

Compliance with Statutes

The ISFG membership shall not be used for advertisement purposes. For more information, please visit <http://www.isfg.org>.

Forensic DNA Phenotyping: DNA Testing for Externally Visible Characteristics

M Kayser, Erasmus MC University Medical Center, Rotterdam, The Netherlands

© 2013 Elsevier Ltd. All rights reserved.

Definition, Motivation, and Principle

Forensic DNA phenotyping (FDP) is a relatively young field of forensic genetics and includes, in its widest sense, the extraction of information on human phenotypes through molecular analysis from biological crime scene samples. Although in its current definition, FDP usually involves DNA analysis of externally visible characteristics (EVCs), in principle, also nonvisible phenotypes, such as disease traits and their risks or behavioral traits, can potentially be extracted from the DNA of biological crime scene samples and can potentially provide forensically relevant information. Furthermore, also other biomarkers, such as RNA or methylated DNA, are potentially useful for phenotype prediction from crime scene samples. Often, DNA-based inference of biogeographic ancestry (or genetic ancestry testing) is grouped into FDP, but the assumption that the geographic region(s) where the genetic ancestors of a person originate is manifested in the person's appearance does not always hold true. Although this assumption may indeed be justified if the geographic region of genetic ancestry reflects one, and only one, of the few regions harboring people of distinct appearance (such as Europeans), it is difficult for the many geographic regions reflecting transition zones of appearance traits (such as the Middle East), or for the many geographic regions with strong appearance resemblances (such as some regions of sub-Saharan Africa with some regions of Oceania). Extrapolating human appearance information from DNA-based biogeographic ancestry information is very difficult, if not impossible, for people of mixed genetic origins (with ancestors from different geographic regions). Currently, there is no scientific understanding about the relationship between genetic admixture and appearance trait manifestation whatsoever. However, genetic ancestry testing can indeed provide useful information for forensic investigations without extrapolating appearance, and has already found its niche within forensic genetics during recent years.

FDP naturally evolved out of the realization that there is a general limitation in conventional forensic DNA profiling, namely that persons unknown to the investigating authorities are usually not identifiable through this approach. As long as police investigations are not 100% successful in providing the true suspect, and as long as forensic DNA (profile) databases are not large enough to fully represent the criminal population, including all the first-time criminals, there always will be forensic cases where the evidence DNA profile does not match that of a known suspect. In such cases, mass screenings through conventional autosomal STR profiling may help, but in reality these are only applied occasionally, due to ethical, legal, economic, and other concerns. In contrast to the early days of forensic DNA analysis, by now the message has even spread to the criminal population that participating in DNA dragnets will result in identification, making this approach less and

less successful. Ways to improve the success rate of DNA mass screenings are in the application of familial searches using autosomal STRs or, in the case of male perpetrators, more successfully using Y-chromosomal STRs, to identify the non-participating suspect through STR profile similarities with participating biological relatives. However, such advanced DNA dragnets are controversially discussed as they violate the law in many countries that allow refusal to testify against one's blood relatives. Clearly, the most efficient way of increasing the success rate of conventional forensic DNA profiling is by increasing the size of forensic DNA databases. Although such databases are constantly growing in many countries, due to various political, societal, and economic reasons, it is unrealistic to expect them to become fully representative of the criminal part of the population, not to speak of the establishment of a universal DNA database for forensic use.

If forensic cases that do not reveal STR (or SNP) profile matches wish to be solved with the help of crime scene samples, additional information potentially stored in the samples that may help finding its unknown donors must be explored. One of the most obvious human characteristics is appearance and it can easily be imagined that EVC information of an unknown sample donor extracted directly from the crime scene sample would be highly useful for investigative intelligence purposes in finding such a person, as it would allow concentration of the investigation in a particular direction. FDP is expected to provide knowledge currently provided by eye witnesses in case they are available. However, FDP can be applied to all cases where suitable biological material is available from the crime scene, but only in a subset of cases eye witnesses are available. Moreover, it is expected that those EVCs that finally will be applied in practical FDP can be predicted more accurately through molecular means than through eye witness memories, because the latter are known to be considerably error-prone and EVCs with established low molecular prediction accuracies are unlikely to be applied. Furthermore, FDP allows the attachment of a statistical estimation to the predicted EVC, indicating how likely it is that the EVC information is indeed correct; this crucial information currently cannot be provided with eye witness statements as the necessary empirical evidence is missing. Hence, FDP potentially has various advantages over currently used eye witness reports in the search for unknown suspects.

The strongest limitations of FDP revolve around the lack of knowledge about the genetic basis of human appearance in general. More is known about the genetics of numerous human disease traits than about the genetic factors determining human appearance. This may come as a surprise, especially when realizing that the very same technologies such as parallel genotyping of hundreds of thousands (currently up to more than one million) of single nucleotide polymorphisms (SNPs) through microarrays, and the very same analytical approaches, such as

genome-wide association studies (GWAS), that are frequently applied with success to identify genes underlying disease traits can also be applied for finding genes involved in EVCs. However, GWASs are expensive and need specially educated technical and scientific staff – requirements that can be afforded within well-funded medical genetic research, but often not in limited-funded anthropological or forensic research. Anecdotal knowledge about the appearance resemblance of family members indicates that human appearance is largely determined by genetic factors, although at least some EVCs are additionally influenced by environmental factors. The last 5 years have seen exciting progress, most successfully provided through GWAS, in the identification of genes involved in a few EVCs such as pigmentation traits and body height. Once SNPs are identified to carry statistically significant trait association, additional statistical approaches and additional replication testing are needed to establish their predictive value for a given phenotypic trait. Once the most EVC-predictive DNA markers have been identified, genotyping assays must be developed and subsequently need to be forensically validated for demonstrating that they meet the specific quality requirements of forensic DNA analysis. This chain-of-exploration, combined with limited research activities in this particular field of non-medical human genetics, has led to the current situation, with only one forensically validated DNA test being available for practical FDP.

The Proof-of-Principle: Eye Color Prediction from DNA

The identification of genes involved in human eye (iris) color variation goes back at least 10 years, but it was really the use of the GWAS approach with its first application to human pigmentation traits in the late 2000s that improved human knowledge about the genetic determination of human eye color significantly. Currently about two handfuls of genes are known with confirmed eye color association, each gene usually being supported by various SNPs. Additional genes, albeit with expectedly smaller effect size than the currently known ones, are still expected to become identified. Hence, the common public opinion that blue-eyed parents can only sire blue-eyed children, and brown-eyed parents only brown-eyed children, cannot be true (as rare anecdotal knowledge also indicates) because this would require a single-gene (or two) scenario with a dominant–recessive inheritance pattern. However, in the majority of cases, blue-eyed parents indeed have blue-eyed children and brown-eyed parents have brown-eyed children, which is caused by the fact that two neighboring genes *OCA2* and *HERC2* acting together in a regulatory relationship have a much stronger influence on eye color variation than any of the other genes involved. Although the additional genes only have a minor impact on eye color, they can explain (often in combination with each other) why sometimes the eye color of children is different from that of their biological parents.

Knowledge on eye color genes from GWAS and other mapping approaches has already been taken one step further, and the most eye color-predictive SNPs have been identified from association data. It was demonstrated in a large sample set of thousands of Dutch Europeans with varying eye colors and by using several dozen eye color-associated SNPs that 15 SNPs

from eight genes provide overall prevalence-adjusted prediction accuracies of over 0.9 for blue and brown eye color using a statistical measure AUC (area under the receiver characteristic operating curves) that runs from 0.5 for random prediction to 1 for completely accurate prediction. Six of these SNPs (rs12913832, rs1800407, rs12896399, rs16891982, rs1393350, and rs12203592) of six genes (*HERC2*, *OCA2*, *SLC24A4*, *SLC45A2*, *TYR*, and *IRF4*, respectively) cover almost all of the eye color prediction accuracy achieved in this study. A single multiplex genotyping assay called IrisPlex has been developed for these six SNPs based on chemistry and lab equipment commonly available in forensic institutions. Together with the published article, a statistical tool has been made available for estimating eye color prediction probabilities from IrisPlex genotypes that accesses model parameters obtained from thousands of Dutch Europeans. [Figure 1](#) demonstrates an illustrative example of the overall power of the IrisPlex system in accurately predicting blue and brown eye color from DNA. The eye color of 3 of the 40 people used for illustrative purposes could not be predicted correctly from their DNA using IrisPlex, with two of them having similarly low probabilities for all three-eye color categories not allowing any conclusion, and one being predicted incorrectly. As a further step toward practical forensic application, the IrisPlex assay has been taken through forensic developmental validation, demonstrating that it is highly sensitive, requiring less DNA than commercially available STR kits, performs successfully in various forensically relevant sample types, and provides concordant results in independent laboratories. Hence, overall, the IrisPlex assay meets the agreed quality standards in forensic DNA analysis. An IrisPlex study using large datasets from populations around Europe is currently under way for evaluating the IrisPlex prediction model.

Some of the IrisPlex SNPs are associated with eye color variation and are unlikely to be causal. A potential problem with the use of associated but not causal SNPs for prediction purposes is that the genetic association may be geographically restricted, leading to a disturbing effect of geography on the reliability of the predictive outcomes. This is especially crucial when associated SNPs are applied to predict a trait that has a geographically restricted distribution such as eye color. Eye color variation is only found in people of (at least partial) European biogeographic ancestry or those from regions geographically close to Europe, whereas outside this region, people usually have brown eye color, representing the ancestral state in humans. The European evolutionary history of eye color variation makes it probable that SNP alleles associated with nonbrown eye colors in Europeans are also found in non-Europeans who express brown eye color, which indeed has been observed for some of the IrisPlex SNPs in a worldwide study. However, the combined use of all six IrisPlex SNPs in the overall prediction model resulted in the prediction of non-brown eye colors only in regions where eye color variation is known (i.e., Europe and neighboring regions such as the Middle East and Western Asia), and brown was the only eye color predicted in all of the worldwide regions where only brown eye color is known (i.e., East Asia, Oceania, sub-Saharan Africa, Native America). This indicates that the IrisPlex system provides accurate eye color prediction probabilities independent of biogeographic ancestry.

Figure 1 Illustrative example of DNA-based eye color prediction using the IrisPlex system. Eyes of 40 volunteers are ordered according to the IrisPlex probabilities for blue, intermediate, and brown eye color starting with the highest probability for blue eye color in the upper-left corner and the highest probability for brown eye color in the lower-right corner. Visual inspection of phenotypic eye color was not considered in the ordering of the eye images. The red box marks the two individuals for whom IrisPlex eye color prediction was not informative because the three-eye color probabilities are similar, and the one individual for whom the prediction was incorrect. Reproduced from Walsh S, Liu F, Ballantyne K, et al. (2011) IrisPlex: A sensitive DNA tool for accurate prediction of blue and brown eye colour in the absence of ancestry information. *Forensic Science International: Genetics* 5: 170–180.

Additional SNPs other than the six included in the IrisPlex system have been proposed to be predictive of eye color. However, either they do not provide additional independent information due to genetic linkage to IrisPlex SNPs, or they do not provide any practically useful accuracy improvement for blue and brown eye color prediction already available with the IrisPlex system, or they are unlikely to provide any eye color

information at all because they were ascertained from the combined data of Europeans and non-Europeans. Applying a broad geographic approach for finding predictive markers for a geographically restricted trait such as eye color bears the risk of interpreting results as eye color informative that in reality rather reflect continental biogeographic ancestry. Future studies may provide currently unknown SNPs to further improve

the already high prediction accuracy of the IrisPlex system for blue and brown eye color and/or to provide similarly high prediction accuracies for additional eye color categories such as green. Future research may also show if one can finally overcome the currently followed categorical approach of DNA-based eye color prediction, aiming to predict from DNA various grades of eye color from the lightest gray to the darkest black. Recently, new eye color genes have been identified that show association with continuous eye color, which raises the expectation that more detailed eye color prediction from DNA may be feasible in the future. Such a continuous approach to DNA-based eye color prediction would not only increase the level of detail of eye color prediction but would also avoid the potential complication with categorical prediction in that different investigating officers, for example, when being told that the sample donor is of blue eyes with 98% probability and 99% accuracy as obtained through FDP such as with the IrisPlex System, may have different shades of blue in mind when searching for the unknown suspect. Practical outcomes of such a continuous prediction approach could be matching color charts or color printouts both produced from the genetic information obtained through FDP.

Additional Appearance Traits with Emerging Genetic and Predictive Knowledge

In comparison to eye color, much less knowledge is available for any other EVC regarding predictive DNA markers and molecular tools. After eye color, genetic knowledge on hair color is currently perhaps the most advanced among all EVCs. Various genes have recently been identified for hair color using GWAS, many of which overlap with genes contributing to eye color variation, as may be expected given the relationship between both pigmentation phenotypes in Europeans. One noticeable exception is the *MC1R* gene, which greatly determines red hair (and to a lesser degree other hair colors such as blond), but seem to have no, or only a very minor, effect on eye color variation. In fact, SNPs from the *MC1R* gene were proposed for red hair prediction by the United Kingdom's Forensic Science Service in the early 2000s, using scientific knowledge previously accumulated. However, it took a further 10 years for advances in hair color genetics to provide a large number of hair color-associated SNPs that have now been tested for their predictive effect on various hair color categories. A model including 11 SNPs (rs12913832, rs12203592, rs1042602, rs4959270, rs28777 and rs16891982, rs683, rs1800407, rs2402130, rs12821256, and rs2378249) from 10 genes (*HERC2*, *IRF4*, *TYR*, *EXOC2*, *SLC45A2*, *TYRP1*, *OCA2*, *SLC24A4*, *KITLG*, and *ASIP*), together with the two compound markers MC1R_r and MC1R_R each including different sets of rare SNPs from the *MC1R* gene, provides AUC values of over and up to 0.9 for red and black, as well as over 0.8 for blond and brown hair color in hundreds of Polish Europeans expressing various hair colors. Furthermore, this model differentiated between similar hair color categories such as red and blond-red as well as blond and dark-blond. Recently, the HIrisPlex System has been introduced, which represents a single multiplex assay

considering all these hair colour DNA variants and the IrisPlex SNPs, altogether 24 DNA markers, for the simultaneous prediction of eye and hair color from DNA. As with eye color, additional SNPs have been proposed to be useful for hair color prediction, for example, from joined analyses of people from different continental biogeographic ancestry; however, their effect seems to be one of biogeographic ancestry rather than of hair color. Future research in finding additional SNPs for hair color prediction is still needed, especially for the currently least-accurately predictable blond and brown hair colors, and – as with eye color – moving from categorical to continuous prediction would be beneficial also for hair color to increase the level of detail and to avoid practical problems during police investigations. One issue that needs to be considered in future hair color prediction attempts is the age-dependent change of hair colors such as from blond during childhood to darker colors during adulthood. Age-dependent hair color change currently is not yet understood on the molecular level and thus is not considered with the currently available list of hair color predictive DNA variants.

Many of the genes involved in eye and hair color are also expected to be involved in skin color variation, as suggested by the correlation between the three pigmentation traits in Europeans, and confirmed by the genetic data available thus far. However, as people from Asia or Africa have uniform dark eyes and hair but can have differences in skin color, genes involved in skin color variation that do not affect eye and hair coloration can also be expected. Although some SNPs have been suggested for skin color prediction already, not enough is yet known about the genetic determination of the full spectrum of human skin color variation, which in fact is expressed in people from different continental regions. Future studies using alternative approaches to GWAS for finding additional skin color genes, such as expression or methylation studies, will be required to deliver more skin-color predictive biomarkers.

Currently, for other EVCs, genetic knowledge is even less advanced. Some first genes have been identified for male baldness in Europeans (*AR*, 20p11), straight hair in Europeans (*TCHH*), and thick hair in Asians (*EDAR*). However, for most EVCs, currently nothing is known about the underlying genes. One noticeable EVC exception, where considerable progress about associated SNPs and genes has been made over the last 5 years but the knowledge is still not advanced enough to allow practical FDP, is human body height or stature. The notion that human height is largely inheritable goes back 125 years to the groundbreaking discovery by the Englishman, Sir Francis Galton, that children's body height can be estimated from mid-parental height. Later, it was estimated from comparisons between monozygotic and dizygotic twins that about 80% of human height variation is heritable. Although applying linkage and candidate-gene approaches to normal height did not provide breakthroughs, these methods did identify genes involved in rare medical syndromes with strong height manifestations such as Marfan syndrome. It again was the GWAS approach that provided genes and SNPs associated with body height. Height GWASs also demonstrated, however, that phenotypic effect sizes of the SNPs found to be statistically significant in their trait association are very small, such as only a few millimeter height change per each SNP. It, therefore, was not

surprising that a dedicated genetic height prediction study using data from all height-associated SNPs (~50) available at the time in thousands of Dutch Europeans revealed an AUC of only 0.65 (where 0.5 indicates random prediction). Recall that AUCs for some eye and hair colors are above 0.9, where 1 means completely accurate prediction. Currently, about 180 genetic loci are known that are statistically significant in their association with human body height. This was established in the largest GWAS meta-analysis ever done thus far, involving more than 180 000 individuals. However, these 180 genetic loci together explain only ~10% of the height variation of these 180 000 people. Although no dedicated prediction analysis has been published yet using this most recent genetic knowledge, it can be expected that the height prediction accuracy achievable with all currently available SNPs is still too low for practical FDP. Hence, many more height-predictive DNA markers need to be identified, and are highly expected to exist given the large amount of still missing heritability, before DNA-based height prediction may become practically feasible.

The currently available EVC examples (but also those known from disease traits) demonstrate that the genetic complexity of a trait, together with the amount of heritability and the environmental contribution, determines not only how easy it is to find the most relevant genes involved and to develop highly predictive DNA markers, but also how many predictive markers are eventually needed to obtain prediction accuracies high enough for practical FDP applications and thus how easy it will be to develop a DNA prediction tool. If the genetic complexity of an EVC (or any other trait) is low, while heritability is high and environmental contributions are low, the most relevant genes can be identified with reasonable efforts. This scenario usually leads to a relatively small number of highly predictive DNA markers identified, for which currently available multiplex genotyping technology suitable for forensic DNA analysis such as SNaPshot can be used to develop DNA tools that can be forensically validated and made available for practical FDP; for example, the currently available IrisPlex and HIrisPlex Systems for eye and hair color prediction. If, however, the genetic complexity of an EVC is high while heritability is high and environmental contributions are low, the search for determining genes and associated SNPs is complicated by the small individual effect size requiring very large studies, and the number of predictive markers needed to achieve reasonable accuracies usually is high, with body height as one example. Consequently, once the knowledge is finally established from hundreds or thousands of predictive SNPs, genotyping technologies that allow the parallel analyses of these large numbers of genetic markers are needed that must also meet the specific requirements for forensic DNA analysis. However, such technologies are currently not available. Obviously, any nongenetic contributions cannot be covered by a predictive DNA test; hence, EVCs with low heritability and high environmental contribution are unlikely to be predicted accurately from DNA or any other molecular data.

Outlook: The Near and Distant Future of FDP

Various ongoing scientific and technological developments raise the expectation that DNA-based prediction of more EVCs

than eye and hair color will eventually become available with suitable forensically validated tools for practical FDP application with skin color being one likely example. Furthermore, there are additional gene-mapping activities currently under way on additional EVCs, such as male baldness, hair morphology, and body height, which will serve as a prerequisite for developing predictive DNA markers and forensically validated molecular tools if the accumulated genetic knowledge allows the prediction accuracy needed for practical applications. Hence, the near future will see a growing list of such group-specific EVCs predicted from the DNA of crime scene samples. Such DNA tools will allow the disclosing of an appearance group that the unknown crime scene sample donor is likely to belong to, resulting in the possibility of a more concentrated police investigation in the search for unknown perpetrators by lowering the number of potential suspects. This FDP-guided shortlist of potential subjects would then be presented for conventional DNA profile analysis in search of a match with the evidence profile. FDP involving group-specific EVCs is not expected to be applied to the bulk of forensic cases because conventional police investigation, in combination with existing and growing forensic DNA databases, will deliver sample donor identification through conventional DNA profiling in a large number of cases. However, its facility will lie in the unsolved cases, that is, those that cannot be solved with conventional means including no matches in conventional DNA profiling, which concern police and relatives of victims. Here, FDP involving group-specific EVCs is expected to provide investigative help, especially when the number of EVCs predictable from crime scene samples with high enough accuracy will grow further, as can be expected from ongoing scientific activities.

At the end of the day, however, it is the individual-specific human appearance that is anticipated to be fully conveyed by FDP, as only knowledge on individual-specific appearance can in principle provide individual identification. It is appealing and not scientifically unjustified to speculate about such a future development. If indeed individual-specific appearance of an unknown sample donor can be predicted from a biological crime scene sample, the obtained phantom facial picture can be provided to the police for matching with their database of ID-card/passport photographs, allowing the retrieval of the name and address of the person in question. If this becomes true, forensic DNA (profile) databases, with all their costs, efforts, and limitations, can be buried in oblivion. The current reality, however, is that individual-specific appearance prediction from DNA, or other biomarkers, represents pure science fiction, as almost nothing is known about the genes determining facial morphology. On the one hand, the identical faces of monozygotic twins (at least for parts of their life) indicate that genetics must play the major role in determining (almost) all individual-specific facial morphology. On the other hand, immense scientific work will be needed to understand the genetics underlying facial morphology and, once understood, to develop predictive biomarkers and, if predictive enough, molecular tools validated for forensic application. Activities have been started to map the genetic architecture of the human face such as by the International Visible Trait Genetics (VisiGen) Consortium. In a recent GWAS carried out by the VisiGen Consortium in almost ten thousand Europeans, five genes have been identified with involvement in facial shapes.

Three of them (*PRDM16*, *TP63*, and *PAX3*) have been implicated previously by other approaches in vertebrate craniofacial development and disease, of which one (*PAX3*) was reported earlier with involvement in facial morphology in a GWAS study on children. The remaining two genes (*C5orf50* and *COL17A1*) potentially represent completely new players in the molecular networks governing facial development. From these first studies it seems, as may be expected, that the genetic complexity of the human face is high, as the identified DNA variants only have small effects. Continued and intensified research on the genetics and molecular biology of human appearance will be needed and will eventually show if drawing a reasonably accurate facial phantom picture solely from a biological crime scene sample will eventually become a reality, or will remain fiction in the CSI-type television shows.

Acknowledgments

The author wishes to express his gratitude to those members of his department who carry out various work on identifying genes and predictive biomarkers for human appearance traits, and on developing and forensically validating molecular tools for human appearance prediction in future forensic applications. Susan Walsh and Ruud Koppenol are particularly acknowledged for their contributions to establish [Figure 1](#), and Susan additionally for useful language comments on the manuscript. The author's scientific work on the genetics and prediction of human appearance traits is funded in parts by the Netherlands Forensic Institute (NFI), the Erasmus MC University Medical Center Rotterdam, and the Netherlands Genomics Initiative (NGI)/Netherlands Organization for Scientific

Research (NWO) within the framework of the Forensic Genomics Consortium Netherlands (FGCN).

The National Missing and Unidentified Persons System (NamUs)

MM Houck, Consolidated Forensic Laboratory, Washington, DC, USA

© 2013 Elsevier Ltd. All rights reserved.

Introduction

It has been estimated that there are approximately 40 000 unidentified human remains in the offices of the nation's medical examiners and coroners or were buried or cremated before being identified. In June 2007, OJP's Bureau of Justice Statistics (BJS) confirmed that, in a typical year, medical examiners and coroners handle approximately 4400 unidentified human decedent cases, 1000 of which remain unidentified after one year. BJS further identified the need to improve record-retention policies. As of 2004, more than half (51%) of the nation's medical examiners' offices had no policy for retaining records – such as x-rays, DNA, or fingerprints – on unidentified human decedents. BJS also noted, however, that more than 90% of offices servicing large jurisdictions did have such a policy. Cases of missing persons 18 years old and younger must be reported, but reporting adult missing persons is voluntary. Only a few states have laws that require law enforcement agencies to prepare missing person reports on adults. Overall, there is a low rate of reporting these cases through NCIC.

The National Missing and Unidentified Persons System (NamUs) is a national centralized repository and resource center for missing persons and unidentified decedent records. NamUs is a free online system that can be searched by medical examiners, coroners, law enforcement officials, and the general public from all over the country in the hope of resolving these cases. The Missing Persons Database contains information about missing persons, which can be entered by anyone; however, before it appears as a case on NamUs, the information is verified. NamUs provides a user with a variety of resources, including the ability to print missing persons' posters and receive free biometric collection and testing assistance. Other resources include links to state clearinghouses, medical examiners and coroners' offices, law enforcement agencies, victim assistance groups, and pertinent legislation.

The Unidentified Persons Database contains information entered by medical examiners and coroners. Unidentified

persons are people who have died and whose bodies have not been identified. Anyone can search this database using characteristics such as sex, race, distinct body features, and even dental information.

The newly added UnClaimed Persons database (UCP) contains information about deceased persons who have been identified by name but for whom no next of kin or family member has been identified or located to claim the body for burial or other disposition. Only medical examiners and coroners may enter cases in the UCP database. However, the database is searchable by the public, using a missing person's name and year of birth.

When a new missing person or unidentified decedent case is entered into NamUs, the system automatically performs cross-matching comparisons between the databases, searching for matches or similarities between cases. NamUs provides free DNA testing and other forensic services, such as anthropology and odontology assistance. NamUs' Missing Persons Database and Unidentified Persons Database are now available in Spanish.

Glossary

16S typing A procedure for characterizing isolates of prokaryotic species and strains using the sequence of the 16S rRNA gene.

Binary fission A form of asexual reproduction in prokaryotes where a cell divides giving rise to two daughter cells, each containing an identical copy of the genetic material.

Clonal A descriptive term meaning a cell or cells derived from an asexual ancestry.

Cytopathic effect A change in the microscopic appearance of cells, especially in tissue culture, after being infected with a virus.

Enzyme linked immunosorbent assay An immunoassay that uses an enzyme chemically linked to an antibody or antigen as a marker for the detection and/or quantification of an antigen or antibody in a sample.

Eukaryote A single-celled or multicellular organism whose cells contain a distinct membrane-bound nucleus in which the genetic material is carried.

Horizontal gene transfer A process through which an organism receives genetic material from another organism that is not their ancestor. Commonly, the new genetic material creates a trait or traits that were not previously observed in the original recipient.

Immunoassay A laboratory technique that uses the specificity of binding between an antigen and its homologous antibody to identify and/or quantify an antigen or antibody in a sample.

Immunofluorescence An immunoassay that uses an antibody chemically linked to a fluorescent dye to detect and/or quantify an antigen or antibody in a sample.

Locus (genetic locus) A location within the genome of an organism.

Microbial forensics A scientific discipline dedicated to the analysis of microorganisms and/or toxins for attribution purposes.

Mitosis A form of asexual reproduction in eukaryotes where the nucleus divides giving rise to two daughter nuclei

identical to the original nucleus. Normally mitosis occurs immediately prior to cell division.

Mutation A change in the DNA sequence of the genetic material of an organism. Commonly, this creates a character or trait that is not found in the parental type.

Multilocus sequence typing A procedure for characterizing isolates of prokaryotic species and strains using the sequences of internal fragments, 400–500 nucleotides in length, of several constitutive genes (i.e., genes involved in basic cell function).

Multiple locus variable number tandem repeat analysis A procedure for characterizing isolates of prokaryotic species and strains using the length variation at several variable number tandem repeat loci on the genetic material of an organism.

Personal protective equipment Specialized clothing, equipment, or substances worn by employees to protect against health and safety hazards.

Polymerase chain reaction A biochemical technique that is used to amplify short sequence of DNA (or RNA) for analysis, even from samples containing only minute quantities of DNA or RNA.

Prokaryote An organism, normally microscopic and unicellular in nature, which is characterized by the absence of a distinct membrane-bound nucleus and other membrane-bound organelles.

Recombination A process through which genetic material is broken and joined to other genetic material resulting in new combinations of genetic material.

Single-nucleotide polymorphism analysis A procedure for characterizing DNA sequence variation that occurs at a single nucleotide on the genetic material of an organism.

Single-nucleotide repeat typing A procedure for characterizing length variation in a genome due to the number of times one kind of nucleotide is repeated at a locus.

Variable number tandem repeat locus A location in a genome where a short nucleotide sequence is organized as a tandem repeat and which often varies between isolates by the number of repeats of the nucleotide sequence.

Nomenclature

B. anthracis *Bacillus anthracis* (genus species), the binomial system for naming of species

CFU Colony forming units, a measure of the viable number of bacteria or fungi in a sample

Introduction

The intentional release of *Bacillus anthracis* in the United States in 2001 demonstrated the vulnerability of society to acts of

bioterrorism. This event, and of course the coincidental attacks on the US World Trade Center Towers, spurred a flurry of effort to reduce gaps in our capability to preempt, prevent, react to, investigate, and recover from acts of bioterrorism and to

minimize our vulnerability. This effort continues today. In the decade since, effort has largely focused on testing, improving, extending, and integrating the capabilities of the agencies involved in the prevention and response to public emergencies such as threats of bioterrorism.

Bioterrorism (and Its Impact)

By definition, bioterrorism is the use, or threatened use, of biological agents by states, organizations, or individuals to intimidate or coerce a government, civilian population, or persons to further political or social objectives. This is distinguished from biocrime, which refers to the use, or threatened use, of biological agents to further individual criminal objectives. Biocrimes include acts such as deliberate infection or intoxication of individuals with intent to harm, incapacitate, or intimidate. Biowarfare refers to the military use of biological agents. A fourth category of bioincident sometimes used is bioaccident that refers to the unintentional release of biological agents. The boundary between biocrime and bioaccident is difficult to distinguish if an unintentional release is associated with a crime, for example, when an outbreak of disease occurs as a result of an illegal importation. This article focuses on the application of microbiology to the prevention and investigation of acts of bioterrorism; however, much of what is presented is equally applicable to biocrimes, biowarfare, and bioaccidents.

The use of biological agents for warfare and other malicious purposes has existed for thousands of years but its potential as a terrorist instrument has been more fully appreciated by governments following the 2001 US anthrax letters. Not surprisingly, the threat of bioterrorism elicits enormous public fear; after all, our historical records are littered with descriptions of mass casualties from disease epidemics such as smallpox, influenza, and plague. These are the same pathogens that have the potential to be used by terrorists. In addition, the potential for economic loss through both stock losses and sale and export restrictions from biological agents targeted against crops and livestock cannot be understated. Good examples are the animal diseases, such as foot and mouth disease, bovine spongiform encephalitis, and brucellosis, and the plant diseases, such as *Puccinia* rust and *Tilletia* smuts.

Biological Agents

The term biological agent refers to any pathogen or toxin that can be used for malicious purposes. Not surprisingly, the list of potential biological agents is formidable, spanning pathogens, and toxins from diverse evolutionary origins. Included are species of fungi, protozoa, bacteria, viruses, viroids, and prions and toxins from plants, animals, fungi, algae, and bacteria. Thankfully, most are low to moderate risk agents. With that said, the list comprising the highest risk agents alone is still daunting. At this current time, the US Select Agents and Toxins list identifies approximately 80 different pathogens and toxins that are considered in the higher risk category. The resources, knowledge, skills, and technologies required to detect, identify, and characterize the pathogens and toxins within this list alone

is well beyond the normal range of activities of individual microbiologists or laboratories. The application of microbiology as a forensic science must integrate the skills of microbiologists from law enforcement, public health, specialist, and research laboratories in order to fulfill the comprehensive investigation that is required for legal proceedings.

Microbiology as a Forensic Science

Microbiology is a long-established scientific discipline that up until this century, had rarely been used as a forensic science. Its traditional roots are in medicine and public health, veterinary science, agriculture, biotechnology, industry, and research. The demands on these laboratories are very different to those involved in criminal investigations; hence, laboratories that agree to be involved in forensic investigations have to implement quite significant change in practice in order to meet investigative and legal obligations. For example, the procedures normally used in a medical laboratory for the identification of pathogens from clinical samples may need to be adapted to suit forensic samples, may need to be extended to provide the information required to satisfy the investigation, may require more extensive validation in order to withstand the rigor of legal scrutiny, and/or may need to be adapted to satisfy the legal obligations for evidence management. Laboratory design, management, security, and accreditation may also need to be altered, adapted, or extended to meet the same legal obligations. Conversely, law enforcement agencies and forensic laboratories have had to introduce new practices to allow the safe collection of environmental samples and traditional forensic evidence from contaminated crime scenes and to introduce new procedures for the transport, triage, receipt, storage, and handling of contaminated evidence. Many law enforcement agencies and forensic facilities have built new laboratories specifically to accommodate contaminated evidence and have employed microbiologists to establish forensic procedures for the detection and presumptive identification of biological agents in the field and in the laboratory.

Like all forensic disciplines, the point at which microbiology begins to contribute to a criminal investigation is dependent on the circumstances of the case. Unlike most other forensic disciplines, clinical presentations may well be the trigger for criminal investigations. For example, a covert release of a biological agent may not be detected until links are made between victims, a pattern of illness is identified, an unusual number or type of presentations occurs, or as a discovery through retrospective epidemiological investigations. In these instances, the clinical, microbiological, and epidemiological examinations that were conducted prior to law enforcement involvement will be crucial to the criminal investigation and may form the cornerstone of the investigation and subsequent prosecution. With that said, most threats of bioterrorism are overt in nature, such as when associated with a threatening letter or phone call. Intended targets may be specific, for example, a government representative, or random, for example, citizens in a shopping mall. Sadly, there is evidence for all these different modes of attack in our recent history, but thankfully, the vast majority have had limited success, have been unsuccessful, or have been hoaxes.

The 2001 US anthrax letters is an excellent example of how microbiology is applied in the investigation of an act of terrorism.

The 2001 US Anthrax Letters

Between October 4 and November 20, 2001, 22 people in the United States developed anthrax. Eleven of these individuals contracted inhalational anthrax, while the remaining eleven individuals developed cutaneous anthrax. Five of the inhalational anthrax victims died from their infection. Initiated as a public health investigation, it quickly became a criminal investigation led by the Federal Bureau of Investigation (FBI) when it was suspected that the infections were most likely a result of one or more deliberate mailings of letters contaminated with *B. anthracis*. Subsequently, letters containing *B. anthracis* were discovered in New York and Washington, DC, addressed to Tom Brokaw of NBC News, the *New York Post*, and the US Senators Tom Daschle and Patrick Leahy. A fifth envelope was mailed to the America Media, Inc. building in Florida; however, this envelope was never recovered. Additional letters are believed to have been mailed to other media organizations in New York as inferred from the pattern of infection; however, these letters were also not recovered. The scientific analyses that were central to the investigation required the involvement of 29 government, university, and commercial laboratories. Over the course of this investigation, the scientific field known as 'microbial forensics' emerged. Not surprisingly, it became the conduit through which the investigation was channeled and combined with physicochemical analyses, narrowed the search for the possible origins of the anthrax powders used in the attacks, which in turn provided the crucial leads used to reveal potential suspects.

The key microbiological findings that contributed to the investigation were

1. The four envelopes that were recovered contained extraordinarily high concentrations of *B. anthracis* spores (4.6×10^{10} – 2.1×10^{12} colony forming units per gram). The spore preparations in the *New York Post* and Tom Brokaw of NBC News letters (i.e., the New York letters) were of high purity and the spore preparations in the Senators Daschle and Leahy letters (i.e., the Washington letters) were of exceptionally high purity. This indicated the perpetrator had knowledge of *B. anthracis* spore production protocols.
2. The high concentration of spores in the preparations would have placed the perpetrator at considerable risk of inhalational anthrax. It was highly likely that the perpetrator would have used personal protective equipment (PPE), would have a means of containment (e.g., biological safety cabinet), and/or would have practiced some form of prophylaxis through administration of antibiotics and/or vaccination.
3. The spore preparations were not 'weaponized.' Silica, a substance added to spore preparations to enhance aerosolization, was found in the preparations but was later shown to be incorporated into the spore coat, hence was more likely a natural phenomenon than a form of weaponization.
4. Sampling of 621 US Postal Service drop boxes that fed into the Trenton mail processing facility (i.e., the facility corresponding to the postmark on the letters) found *B. anthracis* spores in only one mailbox. This was identified as likely to be the mailbox from which all the known attack letters were mailed.
5. The Senator Leahy letter was located in one of 642 trash bags of unopened mail that were collected from the Senate buildings after the Senator Daschle letter was discovered. It was located using an innovative sampling protocol designed to eliminate the need to sift through each piece of mail to find contaminated mail. Swab sampling from each of the 642 bags identified 20 bags that contained higher than trace levels of *B. anthracis*. Air sampling of each of these 20 bags identified one bag that was orders of magnitude more contaminated than others. It was this bag that contained the letter addressed to Senator Leahy and was subsequently shown to contain a quantity of powdered *B. anthracis* spores.
6. The New York letters both contained *Bacillus subtilis* as a minor constituent of the powders. The Washington letters did not contain *B. subtilis*. Whole genome sequencing of the isolate from the *New York Post* letter showed a high similarity (98%), but not identity, to the published sequence of the standard laboratory strain *B. subtilis* 168. Polymerase chain reaction (PCR) assays were developed against 23 loci in the evidentiary strain that differed from the reference strain. The *B. subtilis* isolates from the *New York Post* and the Brokaw letters (i.e., the New York letters) were identical to each other at all 23 loci, indicating they were the same strain. This and differences in the physicochemical properties of the materials from the Washington and New York letters indicated the Washington and New York letters contained materials from two different spore preparations.
7. *B. anthracis* isolates were collected from the 4 envelopes, 17 clinical specimens, and 106 environmental specimens taken from locations along the mail path of the implicated letters. The isolates were identified as the Ames strain. Whole genome sequencing confirmed that it had not been genetically engineered. Although insufficient to identify the source, the identification of the *B. anthracis* in the letters as the Ames strain provided evidence that the source of the strain in the letters was likely to be a laboratory. The Ames strain is uncommon in nature; hence, the source material used in the letters was unlikely to have been acquired from nature.
8. The Ames strain was originally isolated from a dead cow in Texas in 1981 and transported to the US Army Medical Research Institute for Infectious Diseases (USAMRIID) laboratory at Fort Detrick in Frederick, Maryland. Over time, the Ames strain was shared with a number of domestic and international laboratories. The FBI assembled a repository of over 1070 Ames strain samples from 20 laboratories, which included three overseas laboratories. These laboratories were identified to have had the Ames strain in their inventory prior to the attacks. Of the 1070 samples, 1059 were viable. The attributes within the samples in the repository were compared against the characteristics in the evidentiary samples.

9. The *B. anthracis* present in the envelopes was shown to be a mixture of multiple distinct colony morphological types (i.e., morphotypes). The specific genetic sequences associated with these morphotypes provided a means through which relationships among evidentiary samples could be assessed. More specifically, these genetic sequences could be used to exclude potential sources of the *B. anthracis* found in the letters.
10. The genetic tests targeted to these unique sequences provided strong evidence that the *B. anthracis* spores present in each of the four envelopes originated from the same source.
11. The genetic tests targeted to the unique sequences in the morphotypes identified only two samples in the repository that had the same genetic sequences as the mailed material. Subsequent investigations revealed both originated from a flask containing *B. anthracis* spores, identified as number RMR-1029, housed at a USAMRIID laboratory at Fort Detrick. Physicochemical tests demonstrated that material within Flask RMR-1029 could not be the immediate source of the material in the letters but could have been the seed material used for the production of the material found in the letters.
12. The identification of the laboratory and flask from which the seed material originated narrowed the search for the perpetrator to the individuals who had access to Flask RMR-1029 at the USAMRIID laboratory at Fort Detrick and ultimately led investigators to identify Dr. Bruce Ivins as the perpetrator.

Dr. Ivins was a senior microbiologist working on the US government anthrax vaccine program at the USAMRIID laboratory at Fort Detrick. Dr. Ivins took his own life before charges could be filed hence the science behind the investigation was never subjected to the scrutiny of the judicial system. Interestingly, a review of the scientific approaches used during the FBI's investigation of the anthrax letters by the National Academy of Science (NAS) was critical of some components of the microbiological investigation and some of the conclusions drawn. In balancing these criticisms, the NAS recognized that the investigation required the application of new scientific procedures developed specifically for the investigation and that although state-of-the-art procedures were used at the time, the rapid advances in technology that had occurred over the period of the investigation had superseded some of the procedures used earlier in the investigation.

The microbiological analyses conducted during the investigation of the 2001 US anthrax letters was only one component of one of the largest and most complex criminal investigations in history. Nevertheless, the importance of the microbiological investigations must not be understated, for ultimately, it was the guiding hand behind the investigation. It is the first comprehensive application of microbiology as a forensic science and a model for future applications.

The Application of Microbiological Procedure to the Forensic Sciences

Incidents of bioterrorism and biocrimes present a particular challenge to forensic investigations by the very nature of the crime itself. The potential presence of infectious or toxic agents

dramatically complicates the performance of forensic procedures. In order to minimize risk, basic principles of good microbiological practice and microbial containment must be overlaid across all forensic procedures and of course all forensic evidence. A host of safety precautions are conducted in order to minimize personal exposure and to reduce risk of disease. Examples of such precautions are shown below:

- remote manipulation (e.g., robotic manipulation);
- PPE (e.g., air-purifying respirators, protective garments, and disposable gloves);
- barrier protection (e.g., cordons, glove boxes, biological safety cabinets, and high containment laboratories);
- physical removal of contamination (e.g., the filtration of spores from a DNA extract, personnel decontamination showers);
- inactivation of contamination prior to examination (e.g., gamma irradiation of exhibits);
- minimization of aerosol generation (e.g., through excessive traffic, unnecessary movements and use of high risk procedures such as centrifugation, homogenization, and vacuuming); handling samples as liquid rather than powder significantly reduces aerosol risk; and
- the use of disposable equipment and consumables;
- minimization of workspace clutter;
- use of aseptic technique for transfer and handling of microorganisms;
- decontamination of work areas (e.g., disinfection, chemical deactivation, and vaporous hydrogen peroxide sterilization);
- appropriate waste disposal (e.g., autoclaving);
- standard laboratory hygiene practices (e.g., hand washing); and
- prophylaxis (e.g., vaccination and/or antibiotics)

Although necessary, the application of these principles can be a major hindrance to aspects of the forensic investigation. For example, the use of appropriate PPE and clothing reduces dexterity, movement, field of vision, and comfort and can severely limit examination time. Novel solutions are often required for seemingly simple problems. A classic example is the photography of a postal barcode on a processed envelope. The dye used in the imprinted barcode is only visible when activated by ultraviolet (UV) light. Under normal conditions, the barcode is photographed using a standard crime scene camera mounted with a UV flash. A contaminated envelope contained within a Class 3 biological safety cabinet presents a significant impediment to photography. Using the camera outside of the cabinet is problematic because the UV flash cannot penetrate the cabinet window; however, if used inside the cabinet, the camera and data storage card will be contaminated. The solution is to use remote data transfer or remote flash activation. In hindsight, these solutions are simple; however, they can present a major dilemma when time is critical. Where possible, these restrictions should be identified preemptively and solutions should be found.

To forensic microbiologists, the principles listed above are second nature; however, to other forensic scientists, these must be learned and practiced. The resourcing of trained personnel and equipment for rare events such as bioterrorism and

biocrimes is a major burden to governments but is an expectation of modern society in developed countries.

The Microbiological Investigation of Bioterrorism

Suspected incidents of bioterrorism trigger concurrent forensic investigations from public health and law enforcement. The public health investigation aims to identify the causative agent, its source, and potential victims so that appropriate treatment, control, and preventative measures can be implemented. The law enforcement forensic investigation seeks a more detailed characterization of the agent in its quest to attribute the causative agent to a perpetrator. Both are essential to the criminal investigation.

Journalism's 'Five W's, one H' concept of information gathering applies equally to the forensic investigation of acts of bioterrorism. This concept, immortalized in the children's book by Rudyard Kipling, *The Elephant's Child* (1902), personifies the six fundamental questions that the forensic investigation seeks to address.

*I keep six honest serving-men
(They taught me all I knew);
Their names are What and Why and When
And How and Where and Who.*

Not surprisingly, the identification of the agent is of high priority in the forensic investigation. Armed with this knowledge, strategies that minimize risk to forensic personnel while maximizing the collection of relevant evidence can be implemented. A variety of field tests are available to assist with the identification of the agent on site. These include both generic tests for the detection of biological molecules and specialized tests for the detection of specific pathogens and toxins. Field tests are generally designed to provide rapid but presumptive identification of a very limited number of biological agents and more often than not are undertaken by personnel with minimal microbiology training.

Confirmatory level identification is laboratory based, and the expertise to conduct these analyses resides squarely within the public health laboratories. The agent is first isolated and then identified through a series of traditional microbiological techniques. For bacteria, these include techniques such as culture, colony morphology, microscopy (cell morphology and staining reactions, e.g., gram, capsule, and spore staining), motility, sugar metabolism, fatty acid profiling, volatile organic acid profiling, biochemical testing, serotyping, phage typing, and antibiotic resistance patterns. For viruses, these include techniques such as cell cytopathic effect, host cell susceptibility, and immunoassays (e.g., enzyme-linked immunosorbent assay methods and immunofluorescence). This approach is more generic providing opportunity for detection of a much wider range of biological agents than that afforded by current field tests. In both viral and bacterial diagnostic laboratories, species-specific molecular tests such as the PCR are commonly used to reinforce diagnoses from traditional methodology. Collectively, confirmatory level identification is generally to species level.

The remit of public health laboratories includes the tracing of outbreaks hence specialist public health laboratories have additional methodologies to further characterize

pathogens. Methodologies such as 16S typing, multiple locus variable number tandem repeat analysis, single-nucleotide polymorphism analysis, single-nucleotide repeat typing, and multilocus sequence typing provide data that can be used to assess evolutionary relationships between evidentiary samples and between evidentiary samples and reference strains. As technologies improve and costs reduce, there is little doubt that whole genome sequencing will also be incorporated into the routine methodology of specialist public health laboratories; however, at present, this capability still largely resides in research and commercial laboratories. Together, these molecular methodologies provide a hierarchical approach to resolving relationships. The identity of evidentiary samples is revealed through phylogenetic grouping with reference samples. This is how the *B. anthracis* within the 2001 US anthrax letters was identified as the Ames strain. Even if evidentiary samples are not perfectly matched with any of the reference samples, the degree of similarity between them and the reference samples can be used to predict the nearness of the ancestral relationship between them and close relatives. The ancestral relationship in turn provides information on origin. Using the 2001 US anthrax letters as an example, the identification of the *B. anthracis* as the Ames strain provided strong evidence that it was a laboratory strain and was unlikely to have been isolated from nature.

Bacteria, which are prokaryotes, are clonal in nature. They replicate by a process known as binary fission, a process equivalent to mitosis in eukaryotes, where each daughter cell receives an identical copy of the genome. The variation seen between strains is caused by mutation, horizontal gene transfer, and recombination. These biological processes allow bacteria to adapt to altered or new environments. The clonal nature of bacteria is exploited when inferring evolutionary relationships (as described above); however, it is the differences that provide the signatures of individuality. It is likely that the material used in a bioterrorism event will contain a number of dynamic and adaptive clones that are distinctive for that preparation and hence can be used to trace evidentiary material to a particular preparation. This is how the material within the 2001 US anthrax letters was traced to Flask RMR-1029 at the USAMRIID laboratory at Fort Detrick. Viruses have a similar pattern of evolution; hence, similar processes can be used to trace origins to a particular preparation or host.

Returning to the 'Five W's, one H' concept of information gathering (*what, why, when, how, where, and who*), the importance of microbiology in guiding the criminal investigation is evident. The identification of the agent (*what*) and its individual characteristics can be used to trace the origin of the agent (*where* and *who*) and may provide evidence of opportunity and motive (*who* and *why*). It may also be able to give clues as to *when* it was acquired, *when* it was prepared, and *when* it was disseminated; *how* it was prepared, *how* it was stored, and *how* it was disseminated; and *where* it was manufactured. Knowledge of the manufacturing process reveals the type of equipment and consumables that would have been used in the production process (*what*) and hence *where* these may have been resourced and the skills and experience of the creator (*who*). It can also indicate the type of prophylaxis (*what*) that may have been required to avoid infection or the type of illness the perpetrator may have experienced during preparation or dissemination (*who*).

Final Remarks

The incorporation of microbiology into criminal investigations has been and remains an arduous task. Traditional forensic sciences such as fingerprinting, ballistics, DNA profiling, and crime scene examination were purpose built to assist criminal investigations, whereas at the present time, the forensic application of microbiology is secondary to the primary function of most of the laboratories that are involved. This is because the facilities and expertise required to analyze microbiological specimens is largely outside of the scope of 'normal' forensic laboratories and 'normal' forensic practitioners. Rather, the microbiological investigation largely relies on the cooperation of nonforensic laboratories and in particular, the public health and research laboratories. The imposed procedural obligations, resourcing, and preparations required to provide these services is a major burden to these laboratories but is an absolute necessity if perpetrators of crimes such as bioterrorism are to be brought to justice.

Glossary

AFLP Amplified fragment length polymorphism, a molecular biology method for generating a complex set of DNA fragment patterns for identification of plant material.

Biomarker A molecule, typically protein or DNA, that can be used to generate a biological signature for an individual or organism.

Cannabis A plant with psychoactive compounds, a Drug Enforcement Agency (DEA) schedule 1 drug.

Chemotype A chemical that can be used to classify or identify a substance, thus creating a chemical signature.

Collection cards Evidence archival and storage method for the preservation of plant DNA.

DNA Deoxyribonucleic acid, the essential molecule of genetic inheritance.

Forensic botany The use of plant evidence in courts of law.

SNP Single-nucleotide polymorphism, a molecular biology method for detection of single base differences to aid in identifying plant material and for classification purposes.

STR Short tandem repeat, a repetitive DNA sequence that is genetically inherited and can be used as a unique identifier for genotyping and databasing.

Introduction

Plants as forensic evidence are useful for providing linkages between individuals and locations and criminal events. There are many published cases using trace materials such as bryophytes, pollen, fungi, and grasses. The number of plant species on our planet is vast, so the task of classifying and uniquely bar coding these species for trace evidence purposes is an enormous data-basing endeavor. However, Cannabis is an excellent model plant system to establish the best forensic science methodology for standardizing classification of plants by DNA. Cannabis is regularly associated with violent crime, is highly transferable as trace material, and provides potentially useful associative evidence in many homicides. For classification, most laboratories use chemical methods for detection of psychoactive delta-9-tetrahydrocannabinol (THC) to categorize different forms of Cannabis. Not all Cannabis has detectable levels of THC though; roots, seeds, and small leaf fragments may need molecular biology methods to identify conclusively that they are *Cannabis sativa* samples and are the drug form rather than the fiber form. The application of DNA methods to further delineate Cannabis classifications is already showing great potential in linking samples to sources akin to what has been in place in forensic laboratories for human identification for more than 10 years.

Although some states have passed legislation that allows terminally ill patients to obtain and utilize Cannabis under supervision with a registration card and an American Medical Association (AMA)-approved physician prescription, the high THC content drug form remains illegal to possess at the Federal level and penalties are strictly enforced for illegal growers and drug cartels. As with any federally scheduled drug, the concern

for long-term documented health effects such as emphysema, paranoia, and schizophrenia on the general population require this substance to be monitored. In response to drug enforcement needs, especially the ever-increasing presence of drug cartels associated with illegal cultivation sites on public lands, the Office of National Drug Control Policy (ONDCP) has established the National Marijuana Initiative (NMI) to coordinate Federal, State, and local law enforcement efforts against illegal marijuana grows. These agencies are working together to target, disrupt, and dismantle marijuana-growing operations in California, Kentucky, Hawaii, Oregon, Tennessee, Washington, and West Virginia. To put into perspective the scope of the problem, these agencies eradicated more than 6.8 million marijuana plants from public land in 2007 and received 18.5 million dollars in funding from ONDCP and the Department of Justice (DOJ). The cost and risk of allowing Cannabis to be illegally cultivated on State and Federal park land by drug cartels are high. Not only are unsuspecting tourists injured during chance encounters with drug dealers and booby-trapped cultivation sites, but also the environment is being heavily damaged by soil and water contamination as well as from the refuse left behind from the encampments and cultivation materials. University of New Haven (UNH) receives research funding to work in collaboration with these agencies to develop, verify, and validate new DNA methods to aid their efforts and for ultimate use in forensic science laboratories.

History of Cannabis Cultivation

Some history of nondrug and drug forms of Cannabis has been documented using DNA. Ancient samples of Cannabis have

been excavated and examined from the Yanghai Tombs in China. The Cannabis samples were from a 2700-year-old Caucasian shaman tomb and likely were used as an ancient medicine or psychoactive aid for divination. DNA methods were able to detect THC, cannabitol, and tetrahydrocannabinolic acid synthase (THCA) genes in the leaf samples as a molecular biology method for identification of the remarkably well-preserved materials as the drug form of marijuana. Of particular interest is the genetic inheritance and molecular characterization of the THCA gene as it is correlated with the amount of THC produced in the plant. The amount of THC is thus then also used to distinguish between legal versus nonlegal forms of the plant.

For hemp (nondrug form), there are cultivars listed on the European Union hemp cultivar list for several countries. These cultivars are Italian, Spanish, Czechoslovakian, German, from former Federal Republic of Yugoslavia, Polish, Romanian, from former USSR, Hungarian, and French. These are Cannabis samples that have very low THC but high-fiber content and are used for oil and fiber production for textiles and can be bar-coded for easy classification. Hemp is the common name for fiber-based Cannabis. In searching the literature, there are many studies assessing different cultivars bred for fiber for textiles, especially in the 1930s but still grown for those purposes globally today. In addition, there are numerous Internet sites and health-food stores that sell hemp oil and hulled hemp seeds for high-protein food supplements. These are processed forms of Cannabis seed so the seeds cannot be grown for any other purposes. Frequently, seeds with hulls are irradiated to prevent seed germination; these seeds are commonly found mixed in with bird, grass seed, and cattle feed products.

One very important point of Cannabis classification is to distinguish between cultivation for nondrug versus drug purposes for legal consequences. In the early twentieth century, the United States outlawed cultivation, consumption, and trade of Cannabis species because of a mixture of reasons, but primarily due to concerns for human health and society. A vast majority of other countries have followed a similar paradigm, imposing penalties that range from a small fine to incarceration and execution. Since then, there has been a constant battle between prolegalization advocates for 'medical' purposes and law enforcement where 'no medical value' has been proven. In part, this controversy stems from advocates attempting to circumvent the Food and Drug Administration (FDA) standards and the concern that this plant is being introduced to the general public as safe for consumption when there are legitimate scientific studies showing long-term ill health effects from smoking Cannabis.

History of Classification

Biomarkers are molecules that can be used to create a biological signature pattern that can reliably classify biological organisms into the appropriate category. They can be objectively measured and evaluated as a marker for species, subspecies, variety, or cultivar and be used as indicators of normal versus disease states or for measuring changes in the organism in response to a therapeutic treatment. The optimal biomarker is one that is

precise and sensitive, specific (so as to identify few if any false positives), easily quantifiable, inexpensive, and rapid to implement. There are three phases to biomarker development: discovery, verification, and validation. The discovery process is one that identifies novel markers that highly correlate to the species or desired category of classification. The verification step is a performance test of potential markers to establish which candidate markers are most likely to succeed in the final test method. Validation is a standard quality control process that is necessary to define the appropriate range to which the biomarker can be scientifically reliably applied. Biomarkers have not been used until recently (in the past 8–10 years) to classify Cannabis. In part, this is due to advancements in technology such as polymerase chain reaction (PCR) and molecular cloning. As with forensic human identification, proteins and other chemical methods were used first to identify and classify Cannabis samples. In serology, the study of blood and blood proteins, DNA methodology that was more rapid to perform because it was amenable to high-throughput screening has replaced much of the testing that was performed in forensic science laboratories in the 1970 and 1980s. It is quite possible that DNA tests for Cannabis will ultimately replace the chemical identification and classification methods that are in use today for the same reasons.

Traditionally, Cannabis has been classified visually, both macroscopically and microscopically for leaf morphology, plant style of growth and for the presence of cystolith hairs. Cystolith hairs are observed microscopically as 'bear claw' style trichomes on the leaf surface. Trichomes are glandular structures that contain aromatic resins and other chemicals that are evolutionarily in place for plant protection against predators. These hairs are used as one legal manner in which to identify a leaf or bud sample as Cannabis. Once classified as Cannabis, some would further classify Cannabis into *C. sativa*, *C. indica*, or *C. ruderalis* while other scientists agree that this plant is a single species of *C. sativa* but with highly variable physical characteristics related to genetics and environmental factors of the growth habitat. Cannabis is an annual plant grown outdoors from April to September. Natural wild populations do exist in certain regions of the United States but have low THC content and are often referred to as 'ditchweed'. Ditchweed likely represents escaped plants from hemp cultivation sites and are not in the same category as the high-potency marijuana specifically bred for illicit drug street sales. *C. sativa*, *C. indica*, and *C. ruderalis* typically are dioecious (each individual is either male or female) but under environmental stress, female plants can be forced to generate pollen. This gives traditional botanists some challenges in determining how best to classify the sex of the plant. *C. sativa* and *C. indica* generally grow tall (some varieties reach up to 4 m in height) and the female plants start the production of flowers rich in THC (1–23%) as the season changes from summer to autumn. *C. ruderalis* is very short in plant stature; produces only trace amounts of THC and flowers independently of photoperiod. Multiple DNA approaches to identify a sex-linked marker for Cannabis have had moderate success and include random amplified polymorphic DNA (RAPD). Cannabis is also frequently propagated by a physical cloning process and grown in a controlled indoor or outdoor environment (hydroponics). Studies have shown that this process does not mutate or affect

the inheritance of DNA markers in any meaningful way across ten or more cloning generations.

Law enforcement characterizes two forms of *C. sativa*, the drug form and the fiber form using morphological features of stem cross-sections and levels of tetrahydrocannabinol or THC. High-fiber content Cannabis has a solid stem structure in cross-section that represents the high-fiber content of the plant. It is a quick and simple method for classifying drug versus nondrug varieties; however, a systematic study of all varieties has not been published to quantitatively assess the level of measurement variation between different cultivars. The characterization of Cannabis by chemical methods results in a chemotype or signature chemical pattern and is the legally accepted standard for classification of Cannabis as being an illicit drug based on presence of high levels of psychoactive compounds. Chemotypes have been found to roughly correlate to the geographic ancestry of the plant but now that the plant is globally purchased and sold, it is not in itself an effective means for geographic sourcing, but can be useful for classification to include or exclude batches of Cannabis from potentially coming from a common source and aid in geosourcing with additional case information. Delta-9-THC and cannabidiol (CBD) can be characterized from plant material both qualitatively and quantitatively. The THC/CBD ratio can group plants into either two or three categories. The 1971 Fetterman et al. ratio yields two chemotypes: chemotype 1 as a drug type with a THC/CBD ratio of >1.0 ; nondrug chemotype II was a THC/CBD ratio of <1.0 . Small and Beckstead identified an intermediate chemotype with a ratio that hovers at approximately 1.0. The current chemotype classification is chemotype 1 (THC/CBD <1.0); chemotype 2 (THC/CBD = 1.0); and chemotype 3 (THC/CBD >1.0).

In an interesting DNA assay, DNA differences were correlated to the genetics of the active and inactive forms of the THCA synthase gene to aid in classification of drug versus nondrug Cannabis. The THCA synthase gene codes for the enzyme involved in the final step of THC synthesis, the conversion of cannabigerolic acid (CBGA) to THCA, which is further decarboxylated into THC. Three genetic categories were identified that matched with the differing levels of THC measured in the plant. Cannabis homozygous for the inactive form of THCA synthase had levels of $<0.4\%$ THC. Cannabis that was heterozygous with one active form and one inactive form of THCA synthase had levels of THC measuring between 4.1 and 14.9%, whereas the homozygous state for the active forms of the THCA synthase gene in Cannabis resulted in THC of 4.6–18.2%. Clearly the first category, those plants with the homozygous inactive form of THCA synthase, would be unequivocally characterized as the fiber or nondrug form of Cannabis.

DNA Methods to Classify Cannabis

The first step in being able to develop effective DNA methods for Cannabis classification and for ultimate acceptance into court is to establish an evidence collection method that archives the DNA for long-term storage. Plant collection cards have been used in past years for research but have not been verified and implemented in a systematic way throughout the

forensic science community. A recent study shows that collection cards are a good methodology for maintaining this form of plant evidence for later testing and field agents were extremely cooperative in training and utilizing these methods in their work. The collection cards are paper cards with antimicrobial and antifungal properties, which protect the DNA from degradation. For drug enforcement agents, it represents a means in which to collect a DNA sample from Cannabis for identification and classification by DNA but would potentially allow the agents to not have to store large quantities of plant materials in holding cages at testing facilities. It would also be beneficial for attorneys as the sample can be archived for many years and still be retested. Using this as a platform for DNA testing, several DNA methods have shown promise for Cannabis classification. Those methods are amplified fragment length polymorphisms (AFLPs), short tandem repeats (STRs), and single-nucleotide polymorphisms (SNPs) and are further detailed in the next paragraphs.

Amplified Fragment Length Polymorphism

AFLP, or amplified fragment length polymorphism, refers to a method where total genomic DNA extracted from plant tissue is digested with restriction enzymes to generate DNA fragments before performing the DNA copying procedure of PCR. It is a generic DNA genotyping technique and can thus be used on any single source plant species. Genomic DNA is digested with enzymes to fragment DNA into different lengths, adaptor sequences (short synthetic segments of DNA) are added to the ends of the fragments using another enzyme called ligase. Each fragment now has a region on each end that can be recognized and bind PCR primers to amplify a subset of fragments. These fragments are labeled with a fluorescent dye for detection by capillary electrophoresis during the PCR process. Labeled DNA fragments are separated by size and molecular charge by capillary electrophoresis and the fluorescent bar code is captured by a charged coupled device (CCD) camera and analyzed using fragment sizing and genotyping software. The benefit to this technology is that it can be applied to any plant species of interest without a priori knowledge of the genome organization of the species. It also requires a small amount of sample for processing and is similar in analysis to other forensic DNA techniques. The limitations to this technology include difficulty in interpreting mixtures due to the complexity of the fragment patterns, the care required to avoid contamination of single source samples, and the need for reference databasing for comparisons of the evidentiary plant to representative populations. The complexity of AFLP is highly useful for inbred plant species where a majority of the varieties may share common DNA. The more complex the data set due to high levels of DNA fragments and accordingly complex band patterns, the more likely AFLP will be able to detect a small difference in the DNA. On the basis of the AFLP method, one would expect that different band patterns from related individuals would result from single base differences in restriction enzyme recognition sites. AFLP has been successfully used to classify and study many different plant species related to forensic science casework including Cannabis (marijuana), Olea (olive), and Quercus (oak).

Short Tandem Repeat

STR, or short tandem repeat, refers to a DNA method that uses discrete targeted PCR primers to amplify specific regions of interest in the genome based on sequence homology to the primers. During the PCR process, fluorescent dyes are incorporated into the DNA fragment to label it for later detection on the capillary electrophoresis instrument, which separates out DNA fragments based on size and charge. Customized software can bin DNA fragments and assign genotypes much like the standard forensic human identification software available in most forensic DNA units today. Ideal STR primers are specific to a species; amplify fragments in a balanced manner when combined into a multiplex system; require minimal starting sample and are highly individualizing to a population. These DNA methods for human identification have been evaluated and put into place by the forensic community for human identification and source attribution for many years now. They also have been standardized across the United States to allow for national level databasing in a system called CODIS, combined DNA indexing system.

For Cannabis, several different research groups have published the identification of candidate STR markers. Many of these markers will prove highly useful, especially those that are species specific and show high power of individualization. Of these identified candidates, one STR marker stands out due to it being a hexanucleotide marker with an exceedingly high level of discrimination power between unrelated plant samples. Most human STR markers are tetranucleotide repeat sequences and are ideal because as the number of nucleotide bases in the repeat sequence increases, the background level of artifacts decrease for the PCR amplification and capillary electrophoresis detection steps. This hexanucleotide DNA marker has been optimized and performance verified for direct PCR amplification from an evidence collection card. This is a first step in establishing an effective high-throughput DNA assay for simultaneously identifying species, classifying variety, and linking sample to source. Population studies with various sample sets follow to test the expected levels of genetic similarity and differences within Cannabis using this marker.

Single-Nucleotide Polymorphisms

SNPs, or single-nucleotide polymorphisms, refer to a variety of techniques that allow for the detection of a single-nucleotide base alteration that uniquely or in combination with other SNPs can categorize plants into different subspecies or cultivars. Any nucleotide base change that is inherited in a consistent manner can thus be used to classify that particular plant genetic lineage. SNPs can be detected using standard DNA-sequencing technologies or by newer high-throughput microchip and assay technologies. A recent publication describes the use of an SNP analysis to distinguish between samples of nondrug (fiber and oil varieties) versus drug (high THC level varieties) *C. sativa* samples. The SNP test for Cannabis has been developed by Rotherham and Harbison as an assay to identify four base differences contained within a 399-base-pair DNA fragment. This assay uses a snapshot multiplex kit that assays regions in the tetrahydrocannabinolic

acid synthase gene. When tested on a collection of 94 samples (79 drug types; 15 nondrug types), the SNP patterns were able to correctly identify drug versus nondrug samples in all cases.

Linking Sample to Source

One of the greatest challenges for drug enforcement is the ability to identify sites from where drugs originate or are grown, and then further trace the distribution patterns associated with illicit transport and sale of these substances. Chemical patterns of cannabinoids as well as isotope ratios can help to identify where Cannabis samples may have originated from but mostly this is on a large-scale geographic map and is complicated by the influence of ancestral genetics. The advantage of using DNA is that fine mapping studies can be overlaid onto the existing chemical maps to achieve additional site specific source information. This type of information can be useful for analysis of samples both globally crossing country borders as well as locally for state to state trafficking. As with any forensic test, the more informative the classification criteria, the more useful and tightly defined the substance becomes as associative evidence. As the criteria for classification increase, the ability to closely link or 'match' that item to a source sample increases with corresponding greater levels of statistical significance.

With time technology advances and in forensic DNA, these advances occur approximately every 2 years for innovations in equipment, kits, and applications. Now, there is an easily implementable plant archiving system for plant DNA methods verified by the NMI/ONDPC and UNH that uses collection cards analogous to that for human databasing. Validated plant DNA extraction and AFLP methods are readily available in quality controlled kit format. STR and SNP technologies have standardized detection platforms in forensic science and new kits and new applications for existing kits are being developed on a continual basis to enhance the ability of law enforcement and forensic scientists to identify and classify Cannabis and its drug trafficking patterns using biomarkers. The selection, verification, and validation of the optimal biomarkers for Cannabis are well underway and are being implemented for use by a variety of agencies. Mapping initiatives using both chemical and biological traits have been in place for many years by law enforcement. By linking new technology to these existing mapping initiatives, geosourcing and the ability to tightly link seed sources, distributors and users together across large expanses of space and time is a real possibility. If the level of success in forensic human identification and CODIS databasing can be used as a corresponding measure for plant DNA, the future is bright for Cannabis DNA typing methods and plant databases.

Glossary

Allele One of the variant forms of a single genetic locus.

D-loop An approximately 1000 base gene-free section of the vertebrate animal mitochondrial DNA molecule. The name is an abbreviation of 'displacement loop,' so called because the two DNA strands in this region are often displaced from each other to form a loop structure.

DNA capillary electrophoresis A process by which DNA molecules are separated by size as they move through a polymer-filled glass capillary tube. For a typical forensic DNA analysis, the DNA has been fluorescently labeled for detection by a camera at the far end of the capillary. Molecules of equal length register as a colored peak on the resulting data file.

Electropherogram The graphics file that is the end product of most forensic DNA analyses. See DNA capillary electrophoresis.

Genetic locus (pl. loci) The DNA at a particular physical location on a chromosome.

Haplotype A haploid genotype.

Heterozygous A condition in a diploid organism in which two different alleles occur for a given locus.

Homozygous A condition in a diploid organism in which identical alleles occur for a given locus.

Phenotype An organism's physical and physiological characteristics.

Power of discrimination The probability that an identification test will distinguish between two randomly selected individuals.

Deoxyribonucleic Acid

Overview

The basic technology

We present here a brief introduction. More detailed descriptions of forensic DNA technology can be found in the other DNA chapters of this volume.

Standard forensic DNA techniques utilize the polymerase chain reaction (PCR). PCR is an *in vitro* method for making a tremendous number of copies of a selected genetic locus. The process is also commonly called DNA amplification. PCR permits the analysis of a minute starting amount of sample DNA and produces the extremely concentrated DNA solution required for later steps in the genotyping protocol.

PCR can only take place if short synthetic DNA molecules, called primers, complement (i.e., match according to the base pairing rules of double-stranded DNA) the sample DNA on either side of the target locus. The DNA sequence of the PCR primers, therefore, determines the specificity of the test, that is, the locus that will be genotyped and the species on which the test will work. A multiplex PCR simultaneously amplifies more than one locus, and the greater the number of loci the more discriminating the test.

A highly polymorphic locus is one with a large number of alleles. The loci used in forensic DNA analysis can be classified as those in which the alleles differ in length or those that differ

in the sequence of bases. In fact, two alleles that vary in length must also vary in sequence, but these categories are useful because they correspond to differences in the technology of measuring and reporting a DNA fragment's length compared to measuring and reporting its sequence. The data produced are in the form of a graphics file electropherogram (**Figures 1–3**). The set of alleles observed for an individual is that individual's genotype, often referred to in the forensic science world as a DNA profile or DNA type.

Almost all human identity and paternity test DNA profiles consist of a set of short tandem repeat (STR) loci. STR alleles show length variation, and these loci are located on chromosomes within the cell nucleus. A smaller number of tests are based on the sequence of the mitochondrial DNA D-loop.

Fundamental to the interpretation of a forensic DNA test is an estimate of the proportion of the population likely to have a particular profile. This provides, among other things, the random match probability (RMP) or the chance that an unrelated person selected at random would show the same genotype as the suspect. (Although the forensic DNA literature often refers to 'related' and 'unrelated' humans, in fact the distinction is between close relatives and all others. All humans are genealogically related.) The vanishingly small RMP typically reported for an STR profile match does not reflect any direct survey of that genotype's proportion in the population. Such a survey would probably be impossible to perform. Instead, the

Figure 1 The typical data file produced by human STR analysis. This particular PCR multiplex includes 15 STR loci plus a locus for sex determination. Each peak represents an STR allele and was produced by the fluorescent signal of a population of DNA molecules of the same length. The DNA molecules were separated by size during electrophoresis with shorter molecules shown here on the left and larger molecules on the right.

Figure 2 An expanded section of **Figure 1** showing the alleles at two loci. This profile is homozygous at locus D3S1358, as indicated by the single peak, and heterozygous at TH01. Peak labels identify the individual alleles, named according to the number times a particular sequence is repeated within the molecule.

calculation relies on the fact that the alleles usually fit a model of statistical independence; the presence of one allele in no way predicts the presence of the other alleles in the profile. Statistical independence allows one to use the product rule, a fundamental law of probability, plus some basic population genetic models, to multiply the individual allele proportions (variables that can much more easily be empirically measured) and thereby calculate the proportion of the population expected to have a never-before-observed STR profile.

The proper interpretation of a forensic DNA analysis can seem counterintuitive. Judges and juries want to know if the DNA test proves guilt or innocence. They expect the expert to tell them if a particular item of biological evidence came from the suspect. Statisticians almost universally agree that a

forensic DNA analyst should not interpret the test in either manner. One common recommendation is to present the test results in the form of a likelihood ratio (LR), a mathematical term by which the probability of the test results given a scenario advocated by the prosecution is compared to the probability of the test results given a scenario advocated by the defense. $LR > 1$ favors the prosecutor's case, but it is not by itself a measure of guilt.

Put in everyday words, interpretation of a *simple* forensic DNA analysis might be as follows. The genetic evidence is that STR profiles of semen from a rape kit and blood drawn from a suspect match. The prosecution claim is that the suspect is the source of the semen sample. The defense claim is that an unknown man with the same STR profile as the defendant is

Figure 3 The typical electropherogram produced by mitochondrial DNA sequence analysis.

the source of the semen sample. The numerator of the likelihood ratio is 1. This is the probability that the semen and suspect profile would match if he were the source. The denominator is the RMP, for example, 10^{-17} . In words, the resulting huge LR can be translated as 'either the suspect left the semen sample or something extremely unusual happened.' However, determining guilt or innocence may depend on other factors. There may be reason to think that the suspect and victim had consensual sex. It may be that despite the minute RMP, the suspect has an ironclad alibi and a random match is a more reasonable explanation. During an era of less discriminating tests (only 6 markers tested instead of the 13 or more commonly examined today), two men were found to have the same STR profile with an RMP of $\sim 1/30$ million.

The conservative nature of forensic DNA typing

Despite the fast pace of technological innovation in molecular biology, the adoption of new methods of forensic DNA human identity testing is constrained by several factors. Probably most important is the inconvenience and expense required to change the core set of genetic loci used by laboratories. Were this change to happen, newly generated genotypes could not be compared to previous results, including the earlier casework and the existing convicted offender databases. Probably less important, but still relevant, is the fact that an analyst who performs or commissions a well-established procedure can rely on precedent when it is time to argue admissibility in court.

As of this writing, the genotyping technology that is the most attractive alternative to STRs for forensic purposes is single nucleotide polymorphism (SNP) analysis. A potential relative advantage of SNPs is that they can be typed from samples that are too degraded for recovering an STR profile. Although an individual SNP is usually biallelic, that is, it has only two alleles compared to ~ 10 – 40 for a typical STR, it is possible to simultaneously analyze so many SNP loci that the

test is as discriminating as a standard STR multiplex reaction. It is unlikely, though, that SNPs will replace STRs anytime soon. In addition to the problem of generating new population databases, a biallelic locus makes it extremely difficult to interpret a mixture of two or more individuals.

Innovation in forensic DNA analysis

The practical concerns listed above have not halted forensic genotyping innovation. Recent and likely future changes in technology and procedure include the following.

Improved methods for generating a standard profile

Recent progress has been particularly strong in the development of new ways to produce standard profiles. Mini-STRs are recently developed PCR methods for the core loci. Because the amplified regions are shorter than the DNA fragments produced by most human identity testing kits, mini-STRs recover a genotype from a sample too degraded for conventional methods. Standard STR profiles have also been generated using instruments quite different from the common capillary electrophoresis (CE) platform. This includes CE performed in miniature on a silicon chip or much faster STR sizing using mass spectrometry.

New tests for eliminating a suspect

Although, for the reasons given above, new loci are less valuable than a conventional STR genotype for interpreting a match between samples, these concerns do not prevent the use of a novel locus for excluding a suspect as the source of a sample. The latest commercial human identity testing kits include additional STR loci for this purpose.

Increased automation

Forensic DNA laboratories face a large sample backlog, and the volume of items submitted for DNA testing will continue to

increase. Governments steadily expand the list of offenses for which arrestees are profiled and for which convicted offenders are entered in the database. Investigators submit an expanding selection of sample types and seek DNA results from a broader range of crimes. Automation of routine procedures offers the promise of allowing laboratories to process more samples at a lower cost, as well as avoiding the human errors that may occur more frequently when processing samples manually.

Liquid handling robots can perform almost all DNA 'wet lab' procedures. Robots are able to complete these highly repetitive steps that would otherwise require the time of a DNA analyst. Robots are also less likely to make pipetting errors that could result in failed samples and false exclusions or false inclusions due to accidental sample switches.

In addition to the automation of laboratory procedures, software can interpret an STR electropherogram with little or no human involvement. Currently, it is typical for a human to review the profile alleles generated by analytical software and to manually adjust the interpretation according to any perceived problem. Often the software will have flagged any ambiguity. Expert system versions of analytical software can be trained to mimic the decisions made by a human when resolving these ambiguities, thereby allowing a lab to increase workflow without increasing the number of analysts.

Laboratories have already begun to automate the analysis, particularly for individual steps in the processing of routine samples such as convicted offender tissue stored on a paper punch. The future of forensic DNA analysis promises to include more automation. It is likely that robots will perform multiple steps without human intervention, further reducing costs and the risk of mishandling samples. Although not in frequent use, all-in-one DNA chip technologies offer a method for combining all steps to produce an STR profile that is compatible with current databases.

Expanding the scope of analysis beyond individual identification

Familial searches

While a traditional search of a convicted offender database only looks for exact matches of alleles at all loci, a close partial match could correspond to a close relative. Investigators have used this information to investigate siblings, parents, and offspring of the convicted offenders on the generated list. For male offenders, the list could be narrowed by additional analysis of Y-STRs from both the evidence and convicted offender's DNA sample. A matching Y-STR profile would suggest a paternal link between the unknown person and convicted offender and would help to eliminate spurious partial matches at other loci. The results of this familial search, coupled with more traditional investigative techniques, could justify collecting a sample from the relative in question and determining whether his or her profile matches that of the unknown sample.

Determining an individual's phenotype or ethnicity

For years, forensic DNA analysis has distinguished male from female. Other information about a person's appearance can be inferred by analyzing DNA polymorphisms in genes that have an effect on features such as eye color, hair color, and skin pigmentation. Certain haplotypes of the OCA2 and HERC2 genes have been associated with either light or dark eye color,

already resulting in the development of a multiplex genotyping assay for predicting eye color. Polymorphisms in several pigmentation genes are known to control hair and skin color, and one can easily envision the future development of assays to predict these and other traits.

Even loci with no known effect on phenotype, such as the standard forensic STRs, reflect the historical genetic isolation between geographic human populations. Allele proportions vary between human races and ethnic groups, and a profile composed of a large number of loci can predict a person's self-identified race with a high degree of accuracy.

Both familial searches and DNA phenotyping raise concerns about privacy and civil rights. In familial searches, an unknown profile is compared to a database of millions of individuals. Although a familial search could help to identify relatives of the unknown contributor, unrelated individuals will also be included in the search results. There is a question of whether these search results would warrant further investigation of any of the convicted offenders' relatives given the knowledge that the results would include many coincidental matches to convicted offenders whose relatives had no involvement with the crime in question. When using DNA phenotyping, a similar problem would occur, as traits such as eye color and skin pigmentation are certainly not specific to an individual. The information might unfairly be used by investigators to pursue an individual who fits the vague profile generated from the phenotyping, but who is not the evidence donor. Also, until the limits of DNA phenotyping are fully understood, investigators may exclude the actual contributor if the phenotype profile is incorrect.

Some limitations of current forensic DNA methods

The scientific and legal communities, and the general public as well, now treat the performance of DNA profiling as the standard by which many other forensic science techniques should be judged. This status reflects a genetic profile's inherent power of discrimination and also the fact that certain conclusions, such as tracing semen from a rape victim to a suspect who has no other association with the victim, are particularly incriminating. The basic scientific principles and technology of DNA profiling are common to a broad selection of nonforensic scientific fields. This subjects forensic DNA analysis to much more outside expert scrutiny than is applied to analytical techniques that exist only to serve the legal system. This scrutiny was both intense and highly critical during the late 1980s and early 1990s. Because the technology was so new, forensic scientists could respond to early critiques without worrying about potentially triggering the reexamination of a large number of settled court cases (a concern that hinders the reform of analytical methods with a longer history). As a result, forensic DNA analysis is governed by more modern and sophisticated professional standards than many other areas of forensic science.

One should realize, however, that DNA profiling is not 100% free of unavoidable errors, subjective conclusions, or debate concerning proper statistical interpretation of the results. Even if all evidence handling and laboratory procedures are properly done, it is still possible to generate an erroneous genotype. Fortunately, there is good reason for believing that the risk of a false-positive match between two individual

profiles, such as might incriminate an innocent person, is extremely low. For example, if the risk of a false inclusion were not extremely low then there should be an example of a database 'cold hit' that matched someone who either was deceased when the crime was committed or had an airtight alibi. This has never been reported for a full DNA profile using current tests, although as described above it did occur using earlier, less discriminating, technology.

Individual variation in PCR primer site sequences results in a failure to amplify an allele in about 1/100 to 1/4000 individuals depending on the target locus. Such an individual could falsely appear to be homozygous at that locus. This error can be corrected by simply reanalyzing the sample using a different set of primers, but of course for this to happen the analyst must have reason to doubt the original result. One potential clue is allele peak height on the electropherogram. A homozygous peak is usually higher than a heterozygous peak.
